During the spring session of the James Mackenzie Institute for Clinical Research, St. Andrews, discussions will be held on various subjects. The first was opened by Professor David Waterston, who gave an account of Mackenzie's views on general medicine, as expounded in the fourth edition of *Diseases of the Heart*. In his first address Professor Waterston described Mackenzie's concept of the nature of symptoms and his insistence that their production is governed by general laws. The method of applying this concept to the investigation of symptoms with the view of ascertaining their mode of production was then discussed. Mackenzie's main contention was that the phenomena dealt with in medicine are peculiar to itself and are to be studied from a characteristic standpoint. Medicine must therefore be regarded as a distinct branch of science subject to special laws of its own, which govern its phenomena and dictate the appropriate methods of investigation to be employed in their study. The investigation of these laws is one of the main objects of the work of the institute. In his second address, Professor Waterston observed that in his earlier works Mackenzie made a provisional classification of symptoms into structural, functional, and reflex, the term "reflex" being limited to such manifestations as the visceromotor, vi-cero-sensory reflexes, and the like. But in his later work he pointed out that the functional activity of each organ is regulated and controlled so that it is adapted to the needs of the whole body from moment to moment, and that this regulation is effected by reflex activity. He therefore included functional symptoms in the class reflex. The view that the majority of symptoms, other than structural, are due to the disturbance of normal reflexes was, Professor Waterston said, of the greatest value to clinical medicine. It drew attention to the fact that symptoms are end-results, and that for their proper investigation it is essential that the intermediate processes concerned in their production be detected. A particular symptom, such as breathlessness, might occur as a normal event, as a result of experiment, as the result of administration of a drug, or in disease. The basis of medicine must therefore be a knowledge of the processes by which organs are regulated.

GLASGOW VICTORIA INFIRMARY: AUXILIARY BUILDING.

The ninth annual meeting of the Ladies' Auxiliary Association for the Victoria Infirmary of Glasgow was held in the board room of the infirmary on January 20th. The report submitted by the secretary of the association showed that the subscriptions for the year amounted to £2,667, while with other efforts the association had raised in all £3,896. Dr. A. E. Maynard spoke of the growth of the institution, and said that it was felt that to cope with its development the most effective method to increase the accommodation of the hospital was to build an auxiliary hospital, a practice which was now a modern development generally throughout the country. The Victoria Infirmary had already taken the initial step, having acquired 3½ acres of ground at Thorntonhall. This would enable patients when convalescent to be treated under better conditions of light and fresh air outside the city.

Ireland.

ULSTER MEDICAL SOCIETY.

At a meeting of the Ulster Medical Society on January 14th, the President, Mr. J. A. Craig, in the chair, Dr. F. M. Allen in a paper on rheumatism in children dealt with many of the moot points of this condition: the mild forms which were so often overlooked, the difference in symptoms between rheumatism in childhood and adult life, the type of the rheumatic child, and heredity. He discussed the relation of chorea to rheumatism, the occurrence of nodules, the cause of the continued mild pyrexia, and the cough which was often due to enlarged tonsils. In speaking of treatment he expressed the view that there was sometimes too long a delay in returning to mild exercise and school life.

Dr. R. R. L. Leatham could not agree entirely with the views expressed about the rheumatic diathesis. Rheumatism was exceedingly common in hospital, but rare in the better-class private practice. Of cases of chorea only 50 per cent. gave a history of rheumatism; chorea was chiefly found in the Nordic type of child, whereas rheumatism occurred in the Iberian; no nodules were ever found in chorea. Dr. R. Marshall, from observations made at the Ulster Hospital for Children, concluded that there was no rheumatic type of child. He was in favour of tonsillectomy, though statistics differed as to its utility. He believed in the prolonged administration of salicylates and of constant medical supervision over a considerable period. Care should be taken to prevent the choreic child from corporal punishment at school. Dr. Gardner Robb said that the very high percentage of scarlatinal cases indicated the existence of scarlatinal rheumatism.

Dr. W. Calwell read notes on cases of acro-cyanosis independent of any local vascular or general condition. He suggested a provisional classification of (1) weakened resistance at the periphery, with cyanosis, dystrophy, and pain; (2) a disturbance of the nerve roots, as in the condition of cervical rib; (3) disturbance at the vasomotor centre; (4) in acro-contraction and in hysterical monoplegia or hemiplegia, acro-cyanosis was occasionally found where the psychic or cortical disturbance produced both a voluntary motor and a vasomotor weakness.

COUNTY HEALTH APPOINTMENTS IN IRELAND.

As we announced on January 9th, the Local Government Department of the Irish Free State recently issued to county councils a circular directing each to appoint a county medical officer of health holding a degree or diploma in public health and having practical experience of administration. In order to further the second object, the International Health Board of the Rockefeller Foundation offered to send three medical men, selected by an independent committee, to the United States to familiarize themselves with public health procedure. The Local Government Department recognized also that existing tuberculosis officers possessing the D.P.H. were entitled to

special consideration, and it was announced that arrangements had been made with the Society of Medical Officers of Health to enable such tuberculosis officers to acquire further administrative experience. Accordingly six such officers, appointed by the Ministry, have been attached to as many districts in England, and will each receive a travelling fellowship from the Rockefeller Foundation. In addition to these official nominees, two other officers will be attached to other districts in England.

Correspondence.

POST-ENCEPHALITIC PARKINSONISM.

SIR,—Sufferers from post-encephalitic Parkinsonism, as well as their medical attendants, owe a debt of gratitude to Professor Arthur Hall for his account of the good results of belladonna in this most distressing sequela, of which I saw 37 cases in 1925. I also had given belladonna to check the sialorrhoea, and with some success, and at the same time in some cases the Parkinsonism improved; this I had not attributed to the belladonna, but in view of the evidence brought forward by Professor Hall I shall certainly increase the dosage of the tincture of belladonna to 45 minims daily.

As Professor Hall points out, many of these cases had not been recognized as epidemic encephalitis in the early stages, and this I can confirm. Hardly any of my cases had been diagnosed, except by the friends, who had better opportunities than the medical attendant to notice the slight lethargy or lack of energy which had developed; and even the Parkinsonism had not been recognized as such, many of the cases having been sent to me as "neurasthenics."

While on this subject, may I draw the attention of your readers to the condition of the tongue? In my opinion, this has not been emphasized sufficiently, as in many cases it is the deciding factor in diagnosing some of the cases in the early, and even in the later, stages. The manifestations of this truly terrible disease are so protean that I often say that to diagnose it you must think of all the diseases you know of, exclude them all except epidemic encephalitis, and if the tongue is foul, that is the answer to the puzzle. The tongue is very coated early in the affection, and does not clear up when any pyrexia has disappeared, but continues for weeks or months, sometimes during the whole course of the illness; it is swollen and flabby, but not tooth-marked; if not coated it is angry-looking and cracked; generally it is over-moist, but sometimes is dry and cracked, and "typhoid" like. But in one form or another the foul tongue is practically always present.—I am, etc.,

Manchester, Jan. 25th.

ERNEST S. REYNOLDS.

SPENCER'S "CAESAREAN SECTION."

SIR,—My attention has been drawn to a discrepancy in the comparative figures in my review of Dr. Herbert Spencer's *Caesarean Section*, which I take this the earliest opportunity to correct. Dr. Spencer's figure of 5.5 per 1,000 as the frequency of Caesarean section in University College Hospital would appear to refer to operations done for contracted pelvis only, while those from the hospital reports that I quoted were performed for all indications. This at once introduces an element of unfairness in the comparison which I ought to have noticed and for which I sincerely apologize. But there is still another possible fallacy. Dr. Spencer's figures were based on "5,647 women delivered in the maternity of University College Hospital" (that is, exclusive, as I read it, of cases attended in the outdoor practice). The figures for the St. Mary's Hospitals, Manchester, I based upon 138 Caesarean sections in 1,179 cases "delivered at or near full term" in the hospital, exclusive of outdoor cases, and abortions, etc., in the hospital. The Liverpool figures were 93 sections in 752 "labours conducted in hospital"; Sheffield, 41 sections in 717 cases "delivered in the wards"; Edinburgh, 54 sections in 1,460 cases "delivered at or near full term" in the hospital. Dr. Spencer's

figures may possibly include all the cases attended by the maternity department of his hospital, and were a similar basis to be taken for the other hospitals and the indication of contracted pelvis alone considered, the figures for the four hospitals mentioned would be probably less than half those given by me. Thus the Manchester figures would work out at about 36 per 1,000, Edinburgh at 8 per 1,000, and so on.

In justice to Dr. Potter, whose figures Dr. Spencer compares reprovingly with his own, it ought to be pointed out that his 88 sections per 1,000 cases were presumably performed for all indications, not merely contracted pelvis.

Trusting that this correction and explanation may overtake my mistakes,—I am, etc.,

January 19th.

THE REVIEWER.

COUNCIL OF INDUSTRIAL MEDICINE.

SIR,—May we invoke the aid of your columns to bring to the notice of all medical practitioners specially interested in industrial medicine the recent formation of an association of British industrial physicians and surgeons under the title of the "Council of Industrial Medicine." This body commenced its existence a year ago as the British Section of the International Medical Congress on Industrial Accidents and Diseases, which held its fourth meeting at Amsterdam in September last, and it has now been incorporated in the Federation of Medical and Allied Services. Its objects are to promote the study of this important branch of preventive medicine; to enable practitioners thus engaged to meet and discuss common problems; and to provide a source of information on industrial health questions. Already the medical officers of a number of the leading industrial firms in London and the provinces have joined the council, but it is known that there are many practitioners similarly engaged whose names cannot readily be ascertained. To all such full particulars will gladly be sent on receipt of a postcard addressed to the secretary.—We are, etc.,

D. A. COLES,

Chairman.

EDGAR L. COLLIS,

THOMAS OLIVER,

THEODORE THOMPSON,

Vice-Chairmen.

H. S. N. MENKO,

Honorary Foreign Medical Secretary.

12, Stratford Place, W.1, Jan. 19th.

VACCINE TREATMENT OF THE COMMON COLD.

SIR,—Dr. Glover's letter on this subject in the *BRITISH MEDICAL JOURNAL* (January 23rd, p. 165) is very apposite.

The Medical Officers of Schools Association has already appointed a committee to investigate this subject, which has sent out a questionnaire to the medical officers of a large number of boarding-schools asking for a return of any facts they may have and for their co-operation.

If there is any medical officer of a boarding-school who is practically interested in vaccine treatment and could supply us with data, and to whom the questionnaire has not been sent, I will gladly send him or her a copy.

Some of us (school medical officers) are, and have been for years, whole-hearted advocates of this prophylactic treatment, but others need convincing, and this is not easy to do unless we can get more facts. I agree with Dr. Glover that the large boarding-schools offer great possibilities for mass investigation, to secure which is the object of this committee.—I am, etc.,

L. R. LEMPRIERE, M.B.,

President, Medical Officers of
Schools Association.

Haileybury College,
Hertford, Jan. 25th.

HAEMOCHROMOGEN CRYSTAL TEST FOR BLOOD.

SIR,—I feel sure that Drs. Kerr and Mason, the writers of the article on "The haemochromogen crystal test for blood" (*BRITISH MEDICAL JOURNAL*, January 23rd, 1926, p. 134), will forgive me for mentioning that the pyridine-haemochromogen test was investigated very fully by me, and the results published in 1910 as a volume entitled

Atlas der Kristallformen und der Absorptionsbänder der Hämochromogene (Enke, Stuttgart), which had both a German and an English text. It was shown there that not only pyridine, but also its related compounds, including the piperidines, produced haemochromogen crystals, and an attempt was made to utilize the test for distinguishing between bloods of different species, with, however, unreliable results. The mode of formation of the pyridine and piperidine haemochromogens was described as well as the variation and their spectroscopic characters, and the various haemoglobin derivatives from which haemochromogen crystals could be obtained. The writers may be interested to know that Takayama—whose name appears to have become attached to a mere solution—had, previously to me, been with Professor R. Robert of Rostock, who asked me to investigate the test. My own conclusions were that the test—with pyridine alone—was one of extreme simplicity, and, as it was obtainable from fresh or dried blood, various metallic “haemols,” kathaemoglobin or from haematin, might be of considerable value in the field of medical jurisprudence. As I had been less successful with blood stains, etc., over six months old, even when they were dissolved by sodium hydrate or potassium cyanide, I felt that it could not supplant the haemin test, but I summed up by stating, “it forms an exceedingly simple and satisfactory means of confirming the haemin test, while it may be used in cases where the haemin fails to afford a result or gives doubtful results.” The grape sugar addition is, I think, more a means of lowering the solubility of the haemochromogen and of hastening crystallization than a reducing agent; the pyridine series is effective without it.

Your reviewer of my book (BRITISH MEDICAL JOURNAL, January 21st, 1911, p. 142), when it was published in what I soon realized to have been the wrong form, was prophetic in his sentence, “Our only fear is that the research may be lost sight of.” A summary of the evidence was given in the *Proceedings* of the eighth International Congress of Physiology in Vienna in 1910, where one was able to convince von Zeynek, who regarded the crystals as something different from haemochromogen, that they were indistinguishable from this substance even in the position of the invisible spectroscopic band, and that crystals of carboxyhaemochromogen could also be prepared.—I am, etc.,

WALTER J. DILLING, M.B., Ch.B.,
Department of Pharmacology,
Liverpool University.

January 25th.

TREATMENT OF CARBON MONOXIDE POISONING.

SIR,—In your issue of January 23rd (p. 166) Dr. Sydney Smith has raised the question of priority in suggesting blood transfusion for carbon monoxide poisoning. I should like, therefore, to point out that this treatment was actually used by Hüter in 1870, the patient's recovery being apparently due to the transfusion (*Berliner klinische Wochenschrift*, vii, 341). Lauder Brunton also advocated this treatment in 1873. Animal experiments on the subject were reported by Burmeister in 1916 (*Journal of the American Medical Association*, lxxvi, 164), and his conclusion was that transfusion was of great value for animals poisoned with coal gas; nearly all untreated animals died, whereas 75 per cent. recovered after transfusion.

There can be little doubt, however, that administration of oxygen is to be preferred, when it is available, on account of its greater simplicity. I have on one occasion considered giving blood transfusion to a man suffering from coal-gas poisoning, but at the suggestion of Dr. George Graham he was instead given oxygen through a Haldane's mask, with the result that he rapidly recovered.—I am, etc.,

GEOFFREY KEYNES, F.R.C.S. Eng.

London, W.1, Jan. 25th

PREVENTION OF PUERPERAL FEVER.

SIR,—Sir John Robertson and Dr. Layton have hit the right nails exactly in the right places in their letters to the JOURNAL of January 9th (p. 66).

In this area the puerperal mortality is as high as anywhere in England, if not higher. Yet the maternity

department of the Poor Law institution has, during the last year, delivered over 400 cases with no puerperal sepsis and no deaths. Moreover, such cases as needed instrumental delivery have for the most part been delivered by the same practitioners, whose results outside are not nearly so good.

The two-guinea fee, by no means always forthcoming, for these cases is totally inadequate, though certain members of the Royal Commission evidently thought it excessive. It must not be forgotten that it also includes subsequent attendance during the puerperium, which reduces the fee for the actual delivery to about 5s. Cannot the local authority furnish a simple sterile outfit in addition to this?

The cottage house is no place for operative midwifery. Indeed, there is a growing tendency to transfer difficult cases to the hospital. This tendency is just showing itself, but it should be encouraged in every possible way. If also medical students and midwives could be taught that surgeons do not now prepare the skin for operations by swabbing with weak solutions of coal-tar disinfectants, but that they must shave and adequately prepare the perineum; if simple sterile outfits were provided by the public health authorities; if institutional facilities were increased as much as possible—then, I am convinced, a greater advance would be made in this matter than by the appointment of any number of specialists to deal with the trouble after it has arisen.

Surely this discussion has gone on long enough. Is it not time to be up and doing?—I am, etc.,

Rochdale, Jan. 20th.

JOHN C. JEFFERSON, F.R.C.S.

THE RELATIONSHIP OF THE MEDICAL PROFESSION TO UNQUALIFIED PRACTICE.

SIR,—Dr. Hawthorne's amusing sarcasm (BRITISH MEDICAL JOURNAL, January 16th, p. 122) is somewhat premature. His conception of my notions as to the coming legislation for restricting medical practice to the qualified and registered is entirely at sea. My conception of such legislation is that medical practice will be defined. For instance, it would exclude the domestic therapeutics of the mother who doses her progeny on Saturday night with brimstone and treacle. The law would be administered as a piece of public health legislation by the medical officer of health, not by the police. This officer, on a complaint or on information received, would provide two or more test cases for the unqualified practitioner to treat. If the evidence obtained were satisfactory, then the practitioner would be summoned to a court of first instance. No doubt he would engage a lawyer skilled in the defence of such cases. After the case for the prosecution had been presented, then the defendant, as advised by his solicitor, might or might not enter the witness-box. Whether he did so or not would not matter much, as sufficient evidence of his methods of practice would be provided by the test cases. The Bench would then carefully weigh all the evidence, and if not too much impressed by the number of cures related by defendant's solicitor, they would probably fine defendant a pound or thirty shillings—say, for robbing a blind man by pretending to dissolve a skin that had grown over his eyes.

This is a milder picture than that of the mediæval tortures so eloquently described by Dr. Hawthorne. Modern legislation depends less on its punishments and more on its exposures and restraints for its good effects, all of which are of an educative character. No doubt it will take some centuries to modify the gullibility and credulity of the public, but that is no reason why a beginning should not be made and some measure of protection afforded while the process of education goes forward.

Dr. Hawthorne makes fun of my phrase “the analytic method,” but can he suggest a better to describe the legal process that has unveiled the methods of unqualified practitioners in the past? Dr. Hawthorne is good enough to remind me “that it is the right or even the duty of every individual citizen to expose, if he can do so, any fraud which he knows is being practised on the com-

munity." In turn, I should like to remind Dr. Hawthorne that what is everybody's business is nobody's business.—I am, etc.,

Warrington, Jan. 16th.

J. S. MANSON.

RETROBULBAR NEURITIS.

SIR,—Dr. Jordan summarizes the discussion on this subject (*BRITISH MEDICAL JOURNAL*, January 16th, p. 102) by saying that the condition has nothing to do with sphenoidal sinusitis, and he goes on to state that his "own experience confirms this, for no associated lesion is found by x rays in any of the paranasal sinuses." May I say that, having a somewhat extensive experience of x rays in sinusitis during the last eighteen years, I have never yet seen any skiagram, not even excellent stereoscopic plates, that definitely indicated the existence of sphenoidal sinusitis, and thus no skiagram has permitted my exclusion of such disease. There are much safer and surer methods of determining the existence or non-existence of such infections. Skiagrams have proved such valuable aids to the diagnosis of chronic frontal or maxillary sinus infections that it appears a pity to claim value for x rays in connexion with the diagnosis of sphenoidal sinusitis, though they are so helpful for defining the size and outline of the cavities.—I am, etc.,

Clifton, Bristol, Jan. 25th.

PATRICK WATSON-WILLIAMS.

ANAESTHETICS IN CHILDHOOD.

SIR,—Dr. Strange in his criticism of my defence of chloroform (*BRITISH MEDICAL JOURNAL*, January 16th, p. 121) states that "it is on him [the anaesthetist] that the blame will rest if the operation is successful but the patient dies some days later from pneumonia." Needless to say he is referring to ether; those who use chloroform are not troubled with such a sequela. He also admits that "ether is in some cases more dangerous than chloroform." After such an opinion from an anaesthetist I am more than ever inclined to champion chloroform, again with the proviso that it be properly administered.

The fact that Dr. Strange states that the naked flame and not the Shipway apparatus caused the explosion to which I referred, by igniting the inflammable ether, is merely another reason why we should use chloroform, even in such "contraptions." If the risk of death by violence can be eliminated there can be no valid reason why anaesthetists in institutions should not continue to use them; but I was referring principally to general practice, where the employment of cumbersome apparatus, besides being inconvenient in an emergency, might give the patient and friends the impression that a limelight entertainment was coming.

Further, by the use of chloroform sprinkled on a mask it is easy to admit the oxygen of the air at intervals. I am surprised at Dr. Strange's statement that chloroform in the hands of a competent administrator is not safe. All that is necessary (unless one has a danger complex) is to avoid an overdose, then there will be no cause for concern. The matron of a neighbouring hospital, under medical supervision, has administered chloroform almost daily for many years (approximately 30,000 times) without a death on the table. She is a competent administrator and the danger is nil.

After twenty-five years' experience of its use I have yet to see a single fatality, and until I do so I decline to seek out other inventions.—I am, etc.,

Cowdenbeath, Jan. 21st.

JOHN B. PRIMMER.

APPENDICITIS COMPLICATING GASTRIC ULCER.

SIR,—The memorandum by Mr. D. Diamond, M.R.C.S., on a case of simultaneous perforated gastric ulcer and acute appendicitis (January 23rd, p. 140) interested me greatly, in that I published an exactly similar case in a girl of 18 some sixteen years ago (*Lancet*, 1910, i, 103, 119).

As was pointed out editorially on that occasion, seeing that both conditions are common, it is not surprising that a case of their concurrently being present should occasionally turn up, whether or no there be any causal connexion between the two conditions.—I am, etc.,

Clifton, Bristol, Jan. 25th.

C. A. MOORE, M.S., F.R.C.S.

Obituary.

PROFESSOR CAMILLO GOLGI, Pavia.

WE regret to record the death, on January 21st, of Professor Golgi, the eminent histologist of Pavia University. Camillo Golgi was born on July 7th, 1844, at Corteno. He completed his studies at the University of Pavia in 1865, and was appointed extraordinary professor in that university in 1875. After being professor of anatomy in Siena for less than a year, he was appointed professor of histology in Pavia in 1876, and professor of general pathology there in 1881.

Professor Golgi's researches into the minute anatomy of the nervous system were of fundamental importance, and his name will be for ever intimately associated with this great field of knowledge. He invented a method of staining by impregnation with silver chromate, which demonstrates beautifully the structure of nerve cells, their processes being stained a deep black. The application of this method in the hands of Golgi himself, Ramón y Cajal, and others, provided the chief histological evidence for the neurone doctrine originally propounded by Waldeyer. According to this doctrine the entire nervous system is made up of a series of units known as neurones, and each neurone, consisting of a nerve cell and its processes, is anatomically independent of every other neurone, the physiological relationship between neurones being brought about by contact of their processes only. By Golgi's method the reduction of silver is confined to individual cells, together with their processes—namely, the axis cylinders and the dendrites—and the stain does not extend into neighbouring neurones. In the cells of Golgi Type I the axis cylinder is a long single process which becomes part of a medullated nerve fibre; this is exemplified in the pyramidal cells of the motor cortex, the anterior horn cells of the spinal cord, and the Purkinje cells of the cerebellum. Such an axis cylinder ultimately expands into an arborescence around the cell body of a second neurone. In the cells of Golgi Type II the axis cylinder breaks up at once into a wide ramification; such cells are found in the posterior horn of the spinal cord and in the granule layer of the cerebellar cortex, and are believed to have a distributive function, bringing a single neurone into physiological contact with many others.

The neurone theory receives powerful support from the effects of disease of the nervous system, in particular the limitation of Wallerian degeneration, in a nerve fibre separated from its parent cell, to the particular fibre concerned: the whole structure of clinical neurology is indeed based on this conception. Observations by Apáthy, Bethe, and others have tended to call the neurone theory into question, for they demonstrated fine fibrillar networks around and within the bodies of nerve cells which, they believe, establish an actual continuity between adjacent neurones. Golgi himself demonstrated these networks of fibrils on the periphery of cells, but regarded them as being concerned in the structure of the individual neurones and not as establishing anatomical continuity between neurones. While the final truth of this matter is still unsettled, there can be no doubt that physiological and pathological conceptions strongly favour the original neurone theory.

Professor Golgi also described a special form of nerve ending met with in tendons, and known as the "organs of Golgi," and another type of nerve ending in the subcutaneous tissue of the pulp of the finger under the name of Golgi-Mazzoni corpuscles.

The main achievement of Golgi's life was the work he did on the minute anatomy of the nervous system, and he well deserved the Nobel prize he received in 1909; but he did pioneer work also in the investigation of the malarial parasites. After Laveran had made his discovery in 1881, Golgi, in 1886, demonstrated the life-cycle of the parasite in man and the relation between the attacks of fever and its sporulation; later on he distinguished the parasites of quartan and tertian malaria.

GEORGE ROBINSON, M.R.C.S., Bedford.

Dr. GEORGE ROBINSON passed away at his residence in Bedford on January 16th at the age of 87 years. He succeeded his father in the practice, which he cultivated with great competence, shrewdness, and natural kindness. He received his education at Bedford Grammar School and St. Bartholomew's Hospital, where he commenced his medical studies in 1856, qualifying M.R.C.S. and L.M. in 1860. He was a devoted member of the British Medical Association.

For many years he was deputy chairman of the Bedford County Hospital, and he was J.P. for the town of Bedford. Dr. Robinson was endowed with physical energy to an unusual degree. He had on more than one occasion, when a student at St. Bartholomew's, walked all the way home to Bedford. He was fond of boxing, and many a boxing episode has he recounted to the writer of this notice. He was not only aggressive as a pugilist, but the same aggressiveness was marked in his whole-hearted friendship—he was with his friends heart and soul. He was the ideal companion for a tiger-hunt, or any exploit needing daring and go-aheadness. At the age of 65 Dr. Robinson frequently swam a mile before breakfast, then during the day he would play three rounds of golf, and dance for two hours after dinner. He was a keen huntsman, a good billiard-player and fencer—a sportsman, indeed, of no mean order. He was all but an abstainer from alcohol, but he consumed tobacco vigorously almost up to the end. He used to laugh when reminded that his head was like that of Julius Caesar in the British Museum, but the likeness was striking. A few years ago he sustained a fracture of the femur whilst playing golf; the fracture never quite united, and a period of semi-invalidism set in; for a considerable time he had been confined to bed, where he read and smoked and enjoyed the consolations and devoted attention of Dr. Boll, his successor in the practice. He married Miss Cookson of Luton in 1862. There were no children. His wife died in 1911. After a service at St. Paul's Church his remains were interred in Bedford Cemetery.

EDWARD WOOD, M.R.C.S., L.R.C.P., L.S.A., Enfield.

Dr. EDWARD WOOD, who died on January 14th, had a history which is somewhat unique and perhaps worth recording. He was a member of the London Stock Exchange for about twenty years, but from his boyhood was always most interested in everything connected with medicine. Later he determined to become a student, and, to this end, studied for and passed the London matriculation when about 35 years of age. He then gave up his City life and entered King's College Hospital, being strongly advised by the then dean not to start on such a career so late in life; but his enthusiasm was so great that he entered also at St. Bartholomew's, using both medical schools to achieve his object. He took the diplomas of L.S.A. in 1884, of M.R.C.S. in 1885, and of L.R.C.P. Lond. in 1886. He became a member of the British Medical Association, and settled down in Enfield, where he quickly obtained a considerable practice amongst all classes, and was especially beloved by his poorer patients, whom he always treated with the greatest kindness, and, it might be added, with the greatest liberality. He took a partner in 1893, finding his practice growing larger than he could carry on agreeably single-handed. He retired in 1897, but continued to reside in Enfield. However, this step in no way divorced him from his interest in the profession, for he sat for hours daily in his library reading medical literature, and as far as possible keeping himself up to date. Nothing pleased him more than receiving visits from his former colleagues and talking over medical matters with them, confirming his opinions by producing the latest textbook, which he would gladly lend to his visitor for perusal at home. Thus passed nearly thirty happy years amongst his books, in his rose garden, and at his electric piano-player—always of the latest type, and for which he had a most extensive collection of records of the best music.

Until over 80 years of age he regularly attended the annual dinner of the local Medico-Ethical Society, but to the sorrow of all its members advancing years, bringing failing sight and hearing, precluded his attendance on the last occasion. Many very sympathetic references were made about "dear old Wood" by those present. He passed away painlessly, aged 82, leaving a widow and two sons, one of whom is in the medical profession.

It is with regret that we announce the tragic sequel to an unfortunate mishap in the post-mortem room. Dr. C. Iris Fox died at the Royal Free Hospital on January 21st, as a result of pricking her finger while conducting such an examination there several weeks ago. Miss Fox was the daughter of Dr. R. Fortescue Fox. She studied at the London School of Medicine for Women, and took the diplomas of M.R.C.S., L.R.C.P. in 1915. The following year she graduated M.B., B.S. of London University, and in 1922 obtained her doctorate. Dr. Fox held the posts of senior assistant pathologist and assistant director of pathological studies at the Royal Free Hospital. She was formerly assistant pathologist at Swansea General Hospital and second assistant pathologist at St. Mary's Hospital. She had also been medical registrar at the Royal Free Hospital. She was the author of an article on lymphadenoma and tuberculosis, which was published in the *Lancet* in 1921. Among her contemporaries Dr. Fox was admired for the painstaking thoroughness which characterized all her work. The sadness of such a mishap is intensified by the high standard of Dr. Fox's work, which pointed most definitely to an eminently successful future.

Universities and Colleges.

UNIVERSITY OF OXFORD. Rollston Memorial Prize, 1926.

This prize, which is now of the value of about £100, is awarded every two years under the conditions stated below, for original research in any subject comprised in the following list: animal and vegetable morphology; physiology and pathology; and anatomy. No candidate will be eligible (1) who has not either for the B.A. degree or the B.M. degree at Oxford or the M.B. degree at Cambridge, or (2) who is not an advanced student for the degree of B.Sc. at Oxford or as an advanced student for the degree of B.A. at Cambridge, or (3) who has not attained the first of such honours more than one; (4) who has not attained the first of such honours more than one; (5) who has not attained the first of such honours more than one.

The next award will be made in Trinity Term, 1926. Candidates wishing to compete must forward their memoirs to the Registrar of the University of Oxford before March 31st. The memoirs may be printed, typewritten, or in manuscript, should be inscribed "Rollston Memorial Essay," and should bear the name and address of the author; memoirs already published are admitted to the competition. No account will be taken of any research which has not been prosecuted by the candidate subsequent to his matriculation.

At a congregation held on January 21st the following medical degrees were conferred:

B.M.—R. Lewthwaite, K. G. Norton.

UNIVERSITY OF CAMBRIDGE.

At a congregation held on January 22nd the following medical degrees were conferred:

M.D.—F. R. Winton, *C. J. Wilson.

M.B., B.Chir.—N. F. C. Burgess.

M.B.—J. Gray.

B.Chir.—The Hon. C. B. Buckley, R. T. Chadwick, G. L. F. Rowell, R. W. Cunningham.

* Admitted by proxy.

UNIVERSITY OF LONDON.

APPLICATIONS for the Graham scholarship in pathology must be sent in to Sir E. Cooper Perry, M.D., Principal Officer, University of London, South Kensington, S.W.7, before March 14th. The scholarship (which is of the value of £300 per annum, in the first instance, for two years) was founded under the will of the late Dr. Charles Graham to enable a young man to continue his pathological researches and at the same time to secure his services to the School of Advanced College Hospital as a Lecturer in Pathology. Further information may be obtained from the Academic Registrar.

UNIVERSITY COLLEGE HOSPITAL.

Four lectures in the history of medicine (illustrated by lantern slides) will be delivered at University College Hospital Medical School by Dr. Charles Singer on Thursdays, February 4th, 11th, 18th, and 25th, at 4.15 p.m. The first will deal with the history of malaria, the second with the history of gout and diabetes, the third with the history of rickets, and the last with the history of small-pox. The lectures are open to all medical students of the University of London.

UNIVERSITY OF ST. ANDREWS.

At the graduation ceremonial held on January 15th the following degrees and diploma were conferred:

M.B., Ch.B.—Dorothy H. M. Ames, Mrs. Margaret S. Armit (*née* Marshall), Janet L. M. Inglis, alloy, Jane M. Miller, "I. Rattray, W. O. Reid, Renée Ritchie, E. H. T. Rutherford, Jean R. Sheriffs, Jean J. Smith, Dorothy G. Stewart.
M.D.—M. L. Abuja, A. A. B. Scott.
D.P.H.—Hermia M. Morrison.

UNIVERSITY OF DUBLIN.

TRINITY COLLEGE.

At the later winter commencements in Hilary Term, held on January 16th, the following degrees were conferred:

M.B., B.Ch., B.A.O.—C. Lord-Flood (*antea licentiatus*), W. J. van Zijl, Margaret O'Neil (*nunc Hill*) (*in absentia*).

The Services.

TERRITORIAL ARMY MEDICAL OFFICERS' ASSOCIATION.

THE Territorial Army Medical Officers' Association has been formed to provide an organization for the consideration of matters of interest to Territorial medical officers, active and retired. We are asked to remind officers that the first annual dinner will be held on Friday, February 12th, at 8 p.m., at the Café Royal, Regent Street. Tickets (12s. 6d., without wine) can be obtained from Colonel M. B. Ray, D.S.O., M.D., at 37, Russell Square, London, W.C.1. The guests of honour will be Lieut.-General Sir Hugh S. Jeudwine, K.C.B., Director-General of the Territorial Army, and Lieut.-General Sir William B. Leishman, K.C.B., Director-General of the Royal Army Medical Corps.

Medical News.

Dr. J. W. McNEE will lecture for the Fellowship of Medicine on the treatment of renal disease on February 4th, at 5 p.m., at 11, Chandos Street, W. A course in venereal diseases at the London Lock Hospital begins on February 1st and will continue through the month. From February 8th to 27th a combined course in diseases of children will be given by the Paddington Green Hospital, Victoria Hospital, and the Children's Clinic. The London Temperance Hospital has arranged a course from February 8th to 19th (4.30 to 6 p.m.). An intensive course in medicine, surgery, and the specialties will be held at Queen Mary's Hospital, Stratford, from February 15th to 27th. The following courses will be held in March: medicine, surgery, and the specialties at the Hampstead Hospital; bacteriology, Westminster Hospital; diseases of the chest, Brompton Hospital; gynaecology, Chelsea Hospital for Women; ophthalmology, Royal Eye Hospital; and tropical medicine at the London School of Tropical Medicine. Copies of syllabuses and of the general course programme may be had from the Secretary at 1, Wimpole Street, W.1.

The inaugural meeting of the London Clinical Society will be held on Thursday, February 18th, at 8.45 p.m., at the London Temperance Hospital, Hampstead Road, N.W., when Sir Arbuthnot Lane, Bt., will give an address entitled "Is Civilization a Failure?" All medical men and women will be welcomed. The Honorary Secretary is Dr. Philip Fildor, 150, Harley Street, W.1.

The British Science Guild will hold a conversazione at Carpenters' Hall, Throgmorton Avenue, London, on Thursday, February 11th, at 4.30 p.m. Brief addresses will be given on the scientific approach in administrative problems, the use and abuse of the "conference" instrument, losses from avoidable fires, and losses from timber disease. Cards of admission can be obtained from the Secretary, British Science Guild, 6, John Street, Adelphi, W.C.2.

The annual dinner of the Hunterian Society of London will be held at the Hotel Victoria, Northumberland Avenue, on Thursday, February 11th, at 7.30. Among the guests expected to be present are the Lord Mayor and Lady Mayoress of London, and the Bishop of Kensington.

A STONE tablet in memory of Sir G. Anderson Critchett, Bt., surgeon oculist to the King, who died on February 9th, 1925, is to be erected in the School Chapel at Harrow, from the design of Sir Charles Nicholson.

DR. JOHN BEATTIE, research assistant and demonstrator of anatomy at University College, London, has been appointed anatomist to the Zoological Society of London, with charge of the prosectorium at Regent's Park.

DR. E. R. A. MEREWETHER of Gray's Inn was called to the Bar on January 26th.

THE Educational Health and Food Campaign, inaugurated in 1907, is now being continued by the People's League of Health, at the request of the council of the Bread and Food Reform League. Efforts are made to circulate information about the most nourishing and economical foods and the value of finely ground wholemeal bread.

DR. E. HALFORD ROSS, medical member of the Council of the Industrial Welfare Society, is going to South Africa for a year to make observations on miner's phthisis on the Rand. From Africa he will go to India to advise on measures against malaria and mosquitos in some of the tea-growing industries in Assam.

THE fifth International Congress of the Science of Heredity will be held in the second half of next September at Berlin, under the presidency of Professor D. E. Bauer. This will be the first international congress held in Berlin since the war.

A REPORT on paraffin dermatitis and cancer, including its incidence, prophylaxis, and treatment, is published by the International Labour Office at Geneva, as one of its series (No. 20) of pamphlets in the *Encyclopaedia of Industrial Hygiene*. The pamphlet, and others of the series, may be obtained from the London Branch of the Office, 26, Buckingham Gate, S.W.1.

ACCORDING to statistics recently issued by the Metropolitan Insurance Company the mortality from small-pox in Canada and the United States, which was under 1 per cent. in 1923, rose to 1.5 per cent. in 1924 and 3.5 per cent. in the first half of 1925. The increasing severity of the disease was also shown by the fact that in one place 44 out of 97 patients died.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **THE EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the **BRITISH MEDICAL JOURNAL** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the **BRITISH MEDICAL JOURNAL** must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the **JOURNAL**, should be addressed to the Financial Secretary and Business Manager.

THE TELEPHONE NUMBERS of the British Medical Association and the **BRITISH MEDICAL JOURNAL** are **MUSEUM 9561, 9562, 9563, and 9564** (internal exchange, four lines).

THE TELEGRAPHIC ADDRESSES are:

EDITOR of the **BRITISH MEDICAL JOURNAL**, *Aitiology Westcent, London.*

FINANCIAL SECRETARY AND BUSINESS MANAGER (*Advertisements, etc.*), *Articulate Westcent, London.*

MEDICAL SECRETARY, *Mediscera Westcent, London.*

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 4361 Central).

LETTERS, NOTES, ETC.

THE NATURE AND ORIGIN OF CANCER.

DR. FRANK B. SKERRETT (Stratford, E.15) writes: Notwithstanding the brilliant researches of Dr. Gye, many of us who have given some time and thought to the problem still remain unconvinced as to the microbic nature of cancer—and not without reason. There are many well known grounds for disbelief in any specific organism as a cause of cancer, but I do not propose to enumerate them here. The school of adherents to the parasitic theory (largely in evidence in the early nineties) has been rapidly discarded it, so that it would appear that Dr. Gye's discovery—with the interpretation put upon it—must have fallen as a bomb-shell among them. Urged more by doubt than any desire to depreciate so valuable a piece of work, I venture to put forward

the following a for future inquiry of these new fac Leitch says: "It is difficult to see how the observations can be put in a line with many facts already known." It is usually admitted that the nucleus is the most vital and essential part of a living cell, the surrounding protoplasm playing a subordinate part in the way of protection and nutrition, its chief function no doubt being to elaborate the special food material (specific colloids) in the service of the nucleus. When a cell is injured or mechanically divided, the portion attached to the nucleus, even if it be the smaller part, recovers and reproduces the whole cell again, but a part containing no nucleus or portion of a nucleus perishes. The nucleus selects from the proteins of the cell body the special colloids it requires for growth and mitosis. Now in Dr. Gye's experiments it seems quite possible that in the process of grinding up the minced tumour with sterile sand, not only are the cancer cells broken up, but also many nuclei disintegrated, thus setting free in a very finely divided state minute fragments of living nucleoplasm. It is impossible to say to what degree of subdivision this might proceed, but it is quite conceivable that the results of this fragmentation might easily be of filterable dimensions. Now one of the specific characters of nucleoplasm is its power of auto-synthesis, if the medium in which it exists contains the necessary ingredients. May not the smallest fragment of living nucleoplasm automatically grow in contact, under suitable conditions, with the specific proteins of the disintegrated cancer cells, acting as the accessory factor, and may it not organize itself eventually into a biological unit if such specific requirements are present? Seeing that the nucleoplasm is the bearer of hereditary qualities, there is no reason why it should not be able to do so. Dr. Gye's experiments, in fact, show that the cell—that is, into nucleoplasm (acting as the virus) and cytoplasm (the accessory factor)—and, after filtration, reunited them under suitable conditions for growth in the body of the animals experimented on? This would account to some extent for the impotence of the virus alone and the specificity of the accessory factor; and may not the cultured bodies photographed indirectly by Mr. Barnard be the biological units of nucleoplasm? I would incidentally point out here that the recently discovered method of producing cancer experimentally, by painting the backs of mice with solution of tar (which contains a relatively high percentage of phenols and cresols), would appear to bring about the very conditions inimical to any hypothetical cancer-producing germ. In conclusion, I think it must be disquieting to the public mind to be led to think that cancer, after all, may be due to the fortuitous invasion of a ubiquitous germ capable of attacking all and sundry under suitable conditions, and irrespective of the fact that they may have led perfectly healthy and normal lives. I am therefore of opinion that the points herein raised should be considered before it is taken for granted from Dr. Gye's discovery that cancer is a germ disease.

DR. A. T. BRAND (Driffield), in the course of a communication on the same subject, writes: It strikes me as extraordinary that speculation as to the cause of cancer can still take place. To be told that hyperplasia may merge imperceptibly into cancer, that cancer can be caused by the fanning of rats, or by means of gall stones, etc., is like being told that pneumonia is caused by exposure to cold and wet, or that anthrax is caused by a shaving brush, or tetanus by a splinter of wood. Those who speculate on the origin of cancer completely fail to realize that it is a typically specific disease which cannot be caused by any mechanical agent or any intrinsic condition of the tissues, but only by a specific agent. They also fail to realize that the true cause of any disease must be present in every case without exception, and they further fail to grasp the fact that *post* and *propter* are not synonymous terms. That cancer is due to an extrinsic agent, as all specific diseases are, is logically established, and as cancer does not attack the healthy body, it is obvious that most of the alleged causes are simply and entirely pre-disposing. Of these pre-disposing agencies irritation (chronic or continuous, of all kinds) is probably the most potent, as has been known for many centuries. The only possible specific extrinsic agent, which alone fulfils the axiom of universal applicability, is a parasite, and this has been demonstrated by Dr. Glover of Toronto, now of New York, years ago, and confirmed by Dr. Young of Edinburgh. These two research workers, unknown to each other, made, independently, exactly the same discovery, even to the fact that the parasite is pleomorphic, existing in four forms, of which one is ultra-microscopic and filter-passing. It is interesting to note that Dr. Gye of London has dared to break away from the great antiparasitic majority of research workers and has stated his conviction that cancer is a specific disease. He discovered the fourth (filter-passing) form of the cancer parasite and declared it to be the cause of the disease. It seems that he has failed to discover the other and visible forms. He insists that there is a "specific factor," which must be present before the germ can attack successfully. There is, however, no "specific factor." As stated already, cancer does not attack the healthy body. The soil must be prepared for the specific agent, hence what I have always termed the "condition precedent" must exist. This is induced by many things which I need not again enumerate, among which continued irritation is a powerful one. For Dr. Gye's "specific factor" I substitute "vulnerability." That cancer can only be caused by its own specific agent, an extrinsic parasite, must commend itself to anyone who realizes to what an enormous extent parasitism is responsible for the causation of disease. There would be no

difficulty in appreciating this were we endowed with microscopic vision. One Manchester pathologist, who is bitterly opposed to the parasitic origin of cancer, has advanced the theory that the cancer cell is itself the parasite. This was originally suggested by the late Sir Henry Buntin, but it is manifestly untenable, since it will not account for the first or original case of cancer, where there was no cancer cell to cause the disease. The cancer cell, *per se*, is perfectly harmless, just as harmless as an empty Browning automatic. In the first case it is the intracellular parasite which acts, and in the second the live cartridge. The first cancer was caused by the parasite itself.

OCCIPITAL PAIN IN INFLUENZA.

DR. R. MURRAY BARROW (Long Sutton, Wisbech) writes: I have found that the severe occipital pain radiating over the scalp, which is very common with influenza, responds frequently to cloths rung out in hot lotio plumbi. Whether the pain is due to an irritation of the nerve roots or a synovitis of the cervical joints I am not certain.

AN IMPROVED URETHRAL BOUGIE.

MR. E. MUIRHEAD LITTLE, F.R.C.S. (London), writes: Sir Herbert Waterhouse's appreciative note on the late Mr. Bloxam reminds me of an experience which may be of interest to students of the history of minor surgery. Circumstances early honoured me with the acquaintance of Mr. Bloxam, and when I was studying for the final F.R.C.S. examination he kindly allowed me to attend his out-patient clinic at the Lock Hospital and also welcomed me to his wards at Charing Cross. On one occasion, when I was accompanying him round his beds, he came to a case of stricture of the urethra. Discussing with his students methods of treatment, he mentioned that Mr. Wormald of St. Bartholomew's used to use a quill pen as a bougie with considerable success. This statement caused some surprise among his audience, and Bloxam thereupon undertook to demonstrate the method. He sent down to the secretary's office for a long quill pen, for at that time—over forty years ago—these implements were not quite obsolete, and having stripped off all the bars from the rachis or stem, except a small tuft which he wrapped around the end, and having well oiled the whole, he triumphantly passed it into the bladder through a tight stricture. The improvised bougie did not look at all a suitable or comfortable instrument, but the patient made no complaint. I have not anywhere read of this bit of old surgical handicraft, nor have I ever heard it spoken of except by Mr. Bloxam, and I think that it may be thought worthy of rescue from oblivion.

THE COST OF BOROCAINE.

WITH reference to the remark by Drs. Harrison Butler and Gillan in their article on the clinical value of borocaine in ophthalmology (JOURNAL, January 16th, p. 83), that "the cost of borocaine makes it an impossible drug for hospital use," the British Drug Houses, Ltd., state that the list price of borocaine is 2s. an ounce, while that of cocaine hydrochloride is 46s. an ounce (these prices being subject to discount to hospitals), and the cost of the drug contained in 1 c.cm. of a 2 per cent. solution of borocaine is therefore one-fifth of a penny.

A BLACKBOARD ANATOMICAL CHART.

A CONVENIENT chart for teaching anatomy has been designed by Miss E. D. Ewart and produced by Messrs. H. K. Lewis and Co., Ltd., of Gower Street, London, W.C.1. Skeletal outlines are painted in white on flexible blackboard cloth, mounted on rollers, the length of the chart being 4 ft. 10 in. and the width 3 ft. 10 in. An arrangement of side tapes enables the lower portion of the chart to be raised to a convenient level, and the two sides show the front and back of the head, trunk, and limbs, the outlines being slightly larger than life-size. The positions of arteries, muscles, nerves, and organs can be drawn on the chart in coloured chalks and rubbed off as from an ordinary blackboard. It is thus well suited for instruction in surface markings, by way of supplement to the living model. The chart will be sent on approval to recognized teachers who apply for it to the publishers. The price is £2 2s., carriage extra.

INTESTINAL DIVERTICULA: Correction.

OUR apologies are due to Dr. E. I. Spriggs and Mr. O. A. Marxer for an error perpetrated by that imp of mischief, the printer's devil, after the proof of their article had been passed (correctly) for press. In page 133, column 2, the sixth line from foot of page should begin a paragraph and read as follows:

In the third stage of established diverticulitis the

The line which appears in the published JOURNAL is a duplicate of the first line under the figure in the same column, and was accidentally misplaced during final correction.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 41, 42, 43, 46, and 47 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 44 and 45.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at pages 43 and 44.

An Address

ON

TWENTY-FIVE YEARS' PROGRESS IN
ABDOMINAL SURGERY

AT THE MANCHESTER ROYAL INFIRMARY.

Delivered before the Manchester Medical Society on
February 3rd, 1926,

BY

ARTHUR H. BURGESS, M.B., Ch.B., M.Sc. Vict.,
F.R.C.S. Eng.,PRESIDENT OF THE SOCIETY; PROFESSOR OF CLINICAL SURGERY,
UNIVERSITY OF MANCHESTER; HONORARY SURGEON TO THE
MANCHESTER ROYAL INFIRMARY.

THE year 1925, in which you so greatly honoured me by electing me to your presidential chair, completing, as it does, the first quarter of the twentieth century, automatically invites retrospection. In 1900, as the resident surgical officer at the old Manchester Royal Infirmary, I was in very close touch with the surgical work of the institution, and it occurred to me that a comparison between the abdominal surgery of that time and of the present time might not be without interest and instruction to all of us.

In instituting such a comparison account must, of course, be taken of the increased number of beds available for general surgical use in the present as compared with the old Manchester Royal Infirmary (315 as against 186), and of the increase in the honorary surgical staff (from four surgeons and three assistant surgeons in 1900 to five surgeons and five assistant surgeons in 1925), as well as a corresponding increase in the resident and the junior non-resident staff. In 1900 the honorary surgical staff consisted of Messrs. Hardie, Southam, Wright, and Thorburn, with Collier, Platt, and Montgomery as assistant surgeons, and of these seven only one survives (Mr. F. A. Southam); while of the corresponding staff of physicians four survive (Drs. Steel, Bury, Wilkinson, and Reynolds), three of whom are still in practice. Thus the survival rate among the physicians is 66.6 per cent., as against 14.2 among the surgeons—nearly five times greater: one more proof, were any such needed, that the wear and tear of the strenuous and exacting life of a surgeon is very much greater than that of his medical brother.

For my purpose I will compare the abdominal operations (excluding gynaecological) performed in the year commencing January 1st, 1900, with those of the year ending December 31st, 1924. In 1900, out of a total of 2,343 operations of a general surgical character, 266 were upon the abdomen—that is, 10.97 per cent.; whereas in 1924 out of 5,353 operations 3,051—that is, 56.99 per cent.—were abdominal; the proportion of abdominal to other operations had increased more than fivefold. This increase is rather more marked in the "acute" (or "urgent") than in the "chronic" (or "non-urgent") type of case, since in 1900 "acute" conditions accounted for 30.8 per cent. of all the abdominal operations, but in 1924 for 40.6 per cent.

"ACUTE" ABDOMINAL SURGERY.

In 1900 82 operations were performed for acute abdominal conditions, with a mortality of 36.5 per cent.; in 1924 there were 1,241 such operations, with a mortality of 8.1 per cent.

Table I presents an analysis of the acute abdominal operations for the years 1900 and 1924 respectively, giving the proportion that each type of case bears to the total number of such operations, and the corresponding mortality. The total number for 1924 includes 85 cases not analysed in the table (acute cholecystitis 56, acute pancreatitis 6, other acute abdominal conditions 23), since these operations were unrepresented in the 1900 list. Presented in this form the great improvement in the 1924 percentage mortality of each type speaks for itself, ranging roughly from one-half that of the 1900 mortality in the case of acute intestinal obstruction to one-twelfth in the case of acute appendicitis.

TABLE I.—Operations for Acute Abdominal Conditions for the Years 1900 and 1924.

	Number of Operations.		Percentage of Total of Acute Abdominal Operations.		Mortality per cent.	
	1900.	1924.	1900.	1924.	1900.	1924.
Strangulated hernia ...	50	105	60.9	8.5	22.0	9.4
Acute appendicitis ...	14	798	17.07	64.3	64.2	5.1
Acute intestinal obstruction	13	144	15.2	11.6	44.4	20.3
Perforation of gastric ulcer	5	28	108	6.09	8.7	14.2
Perforation of duodenal ulcer	0	80				
Total acute abdominal operations	82	1,241			36.5	8.1

Strangulated Hernia.

The outstanding feature of the 1900 list is the great predominance of strangulated hernia—in fact, operations for hernia were the only common abdominal operations of that day, either acute or chronic. Those for strangulated hernia constituted 60.9 per cent. of all the acute abdominal operations, and those for the radical cure of hernia comprised 58.6 per cent. of all operations for chronic abdominal conditions, while, taken together, hernia accounted for 59.3 per cent. of all the abdominal surgery. In 1924 strangulated hernia constituted only 8.5 per cent. of the acute abdominal operations (slightly less than the proportion of perforations of the stomach or duodenum), and the radical cure only 18.8 per cent. of the chronic, while together hernia accounted for only 14.2 per cent. of all abdominal surgery.

Acute Appendicitis.

The outstanding feature of the 1924 list is the enormous proportion of operations for appendicitis—44.3 per cent. of all the abdominal operations; acute appendicitis accounted for 64.3 per cent. of all the operations for acute abdominal conditions, and quiescent appendicitis for 31.7 per cent. of those of a chronic type. In 1900 there were 14 operations for acute appendicitis—all for either appendicular abscess or peritonitis, there being no case of removal of an acutely inflamed appendix prior to abscess or peritonitis; the appendix was removed as an "interval" operation on 24 occasions. In 1924 there were 798 operations for acute appendicitis, with a mortality of 5.1 per cent., and 575 appendicectomies for quiescent cases, with a mortality of 1.4 per cent.

TABLE II.—Operations for Acute Appendicitis in 1924.

	Condition and Operation.	No. of Operations.	Mortality per cent.
Group 1 ...	Removal of acutely inflamed appendix, without drainage	337	2.07
Group 2 ...	Appendicular abscess, appendicectomy and drainage	360	4.7
Group 3 ...	Appendicular abscess, drainage only	42	16.6
Group 4 ...	Appendicitis with diffuse peritonitis, appendicectomy and drainage	59	16.9
Total ...		798	5.1

Although at the beginning of the present century the rational treatment of acute appendicitis by early operation was being practised both on the Continent and in America, there was considerable delay before any general adoption of its principles in this country. This was mainly due to the strongly adverse attitude towards any operative interference in the acute stages of appendicitis that was taken up by Treves, who at that period was undoubtedly the outstanding figure in British abdominal surgery. Treves taught that operation should not be undertaken unless there was evidence of suppuration, and that even then the surgeon should wait until the abscess had become well localized. Owing to his powerful influence this was recognized as the usual practice in this country, whereas abroad

The appendix still holds its pride of place, though much less outstandingly so than in the "Acute abdominal" list (Table I), constituting 22.3 per cent. only of the non-urgent, as against 64.3 per cent. of the urgent abdominal operations. The percentage of operations for the radical cure of hernia has dropped from 58.6 in 1900 to 18.7 in 1924; 333 such operations were performed in 1924 with but one death, that of a male with a large umbilical hernia, who died of diabetic coma.

Chronic Ulcers of Stomach and Duodenum.

No operation for this condition was performed in 1900, whereas there were 250 in 1924, with a mortality of 4 per cent. These comprised 173 gastro-enterostomies (mortality 2.8 per cent.), 31 partial gastrectomies (mortality 3.2 per cent.), and 46 treated by other procedures. The operation of gastro-enterostomy, first performed by Wölfler in Vienna in 1881 for pyloric obstruction from carcinoma, was for eleven years restricted to cases of actual organic pyloric stenosis. In 1892, however, Doyen applied it successfully to a case of chronic gastric ulcer without organic pyloric stenosis, on the view that the symptoms associated with gastric ulcer were largely due to a spasmodic obstruction at the pylorus induced by the presence of the ulcer. In the following year Codivilla extended its use to chronic duodenal ulcer, again with success, and thereafter it came to be increasingly recognized as a most useful measure in the treatment of chronic gastric and duodenal ulcers; indeed, for many years whenever such ulcers were considered to require operative treatment at all it was the only procedure adopted. Unfortunately, however, its very success in true ulcer led to its abuse as a "cure-all" for all types of dyspepsia, and it is even on record that gastro-enterostomy has been performed for the vomiting of pregnancy, of cerebral tumour, of uraemia, and of locomotor ataxia. Naturally, therefore, the operation fell into some disrepute, from which it was rescued only when it came to be firmly restricted to cases of actual and demonstrable organic lesions in the stomach or duodenum. Even when so restricted it early became apparent that its results, both immediate and remote, were definitely better in duodenal than in gastric ulcer—that whereas it was almost invariably followed by healing of a duodenal ulcer such did not always eventuate in gastric ulcer. For a short period excision of a gastric ulcer without gastro-enterostomy was given a trial, but was soon abandoned, since recurrent ulceration and even perforation occurred.

Essentials in the Operative Treatment of Gastric Ulcer.

It has now come to be recognized that there are two essentials in the surgical treatment of gastric ulcer: (1) the removal of the ulcer itself, either by excision, which to me seems preferable, or by the cautery (Balfour); and (2) the performance of a gastro-enterostomy as a preventive of further ulceration. The ulcer should be removed, not only to rid the patient of its presence, but to anticipate any possible future malignant changes in it. This relation of gastric ulcer to gastric cancer is still a subject of much discussion; on the one hand, the pathologists to the Mayo Clinic, Wilson and MacCarty, make the alarming statement that 71 per cent. of specimens of carcinoma of the stomach removed there showed evidence of preceding ulceration, and that 68 per cent. of ulcers removed under the impression that they were simple ulcers showed early carcinoma at their periphery; on the other hand, Dible and Morley, investigating a series of cases at the request of the Manchester Pathological Society, found that of 126 ulcers removed on a clinical and macroscopic diagnosis of simple ulcer, none showed any microscopic evidence of malignant change, while out of 33 gastric cancers in 2 only (that is, 6 per cent.) did the clinical and histological evidence point to pre-existent ulceration. Most of us will agree, I think, that the latter view much more nearly represents the truth of this question.

Much discussion has taken place as to how gastro-enterostomy exerts its beneficial action—whether by mechanical drainage, or whether by its "physiological" or, as Sherrin prefers to call it, its "chemical" effect in allowing the alkaline bile and pancreatic juice to enter

the stomach and thus neutralize the gastric hyperacidity usually, although not invariably, present; the probable truth is that both factors play their part, the mechanical factor being the one at first mainly concerned, and leading to healing of the ulcer by overcoming muscular spasm and by rapidly emptying the stomach, while the chemical factor prevents recurrence by lowering the acidity of the gastric contents.

The two essentials already referred to—the removal of the ulcer and the performance of gastro-enterostomy—can be carried out either as separate procedures (for example, wedge excision of the ulcer *plus* posterior gastro-enterostomy), or they can be combined in the single operation of partial gastrectomy as advised by Sir Berkeley Moynihan. This undoubtedly, in some case, proves a technically easier and shorter operation than the former. As a routine procedure, however, it has the great objection that it entails the loss of a large amount of healthy stomach, often many times greater than the actual ulcer, and unless we are obsessed with the American ideas as to the great frequency with which gastric ulcers become malignant this would seem a quite unnecessary mutilation. The mortality of partial gastrectomy in the Manchester Royal Infirmary in 1924 was 3.2 per cent., as against 2.8 per cent. for gastro-enterostomy—not a great difference; but were partial gastrectomy to become the adopted routine procedure for gastric ulcer by all of those who at the present time are, throughout the country, undertaking abdominal operations I fear the mortality would show a very material increase.

Operative Treatment of Duodenal Ulcer.

The immediate results of gastro-enterostomy in duodenal ulcer are remarkably good, the proportion of cures being returned at the Mayo Clinic as 94 per cent., and it is certainly very rare for a properly performed gastro-enterostomy to fail in bringing about healing of the ulcer. There is a "fly in the ointment," however, and this is the occasional later development of secondary ulceration either at the stoma (gastro-jejunal) or in the jejunum within a short distance of the stoma (jejunal). The frequency of this complication is estimated at 2 per cent. in the Mayo Clinic, and it may develop almost immediately or be postponed for several years. Its cause is the persistence of hyperacidity after gastro-enterostomy, this operation in certain cases not producing a sufficient lowering of the pre-operative gastric acidity, and I certainly consider that its incidence can be minimized by careful attention to diet, together with the administration of alkalis for a long time following the operation. There is too strong a tendency to consider the operation as the end of all treatment—it is really only the commencement of a new period. To avoid this complication some surgeons have recently shown an inclination to replace gastro-enterostomy in the treatment of duodenal ulcer by either, (a) on the one hand, a reversion to such procedures as pyloroplasty with excision of the ulcer, Finney's operation, and gastro-duodenostomy, which are stated to be less liable to be followed by secondary ulcer, though none of them can claim immunity therefrom; or, (b) on the other hand, more radical measures, such as duodenectomy, or partial gastrectomy; these, however, in the presence of duodenal ulceration and cicatrization are difficult operations, and were they to become widely adopted I fear their increased mortality would prove a more serious matter than the 2 per cent. incidence of secondary ulceration they are intended to prevent. Moreover, this complication has been known to have followed partial gastrectomy, and will, sooner or later, follow a duodenectomy, should that operation continue to be performed at all extensively.

The surgical treatment of these chronic ulcerative conditions may, then, be summarized as local excision of the ulcer *plus* gastro-enterostomy for gastric ulcer, gastro-enterostomy *plus* careful after-treatment for duodenal ulcer.

Time will not permit me this afternoon to do more than mention the marked advances that have occurred during the past twenty-five years in the surgery of the biliary passages, of the intestines, and more recently of the spleen, but were I to do so it would be but a repetition of the same tale of steadily continued progress.

New Methods of Diagnosis.

During the period under review important advances have been made in the methods applicable to the investigation of abdominal conditions, and of these may be mentioned, as of special help to the surgeon, the more extended use of the sigmoidoscope, test meals for the estimation of gastric acidity—whether the old single test of Ewald or the more recent “fractional” method—the Einhorn duodenal bucket and its modification for the investigation of the duodenal contents, the Meltzer-Lyon test to determine the physical characters of bile from the various parts of the biliary tract, and the van den Bergh tests for the detection of bilirubin in the blood serum and the differentiation of obstructive from non-obstructive jaundice. Unquestionably, however, by far the greatest debt of the abdominal surgeon of the present day is to the radiologist, who, by his improved technique, and especially by the combination of x rays and opaque (bismuth or barium) meals and enemata, has produced a veritable revolution in abdominal diagnosis. One need only mention the wonderful degree of accuracy of the present-day radiological diagnosis of all types of oesophageal obstruction, of gastric and duodenal ulcers and neoplasms, of hour-glass stomach, and of hair balls in that viscus, of all obstructive conditions of the bowels, and of all diverticula therefrom. But radiology is as yet scarcely out of its infancy, and we confidently look to it for further triumphs; meanwhile we note with satisfaction the gradually increasing frequency with which the radiologist can demonstrate the presence of gall stones, and still more so the promise he holds out to us, by further elaboration of the technique of “cholecystography,” of being able to recognize cholecystitis in its pre-calculus stage.

Improvements in Surgical Methods.

Concurrently with improvements in the diagnosis of abdominal lesions there has been a marked advance in the technique of surgical procedures designed for their relief. So outstanding has this been, in fact, that it is scarcely surprising that in the past the actual performance of the operation has perhaps loomed too largely in the surgeon's eye, to the comparative neglect of other important, even if less dramatic, factors that contribute to success. In recent years, however, there are evidences of betterment in this respect, and a steadily increasing amount of attention is now being paid to the more careful selection of patients that are submitted to operation at all; to the better choice of the operative procedure suitable to their particular case; to a more thorough pre-operative preparation, so that the patient may be brought into the best possible condition to withstand the immediate effects of the operation itself; and to the necessity, in many cases, of a more or less prolonged period of medical after-treatment and observation, so that the fresh start towards a healthy existence which the operation has enabled them to make may not be carelessly jeopardized. Patients who, from the operative point of view, represent poor surgical risks may nevertheless frequently be restored to health by the adoption of the “two-stage” principle; at the first operation nothing more is attempted than the relief of that factor which is immediately threatening death, leaving the radical cure of the condition—the removal of its cause—until such time as the general state of the patient has been sufficiently improved by the preliminary procedure as to render success probable.

This “multi-stage” principle, which has been applied so successfully in the case of growths of the colon associated with any degree of obstruction, and of prostatic patients presenting evidence of renal back pressure, might with advantage, I think, be further extended—as, for instance, to some cases of carcinoma of the stomach with severe obstructive vomiting and consequent ill nutrition, and especially to cases of calculous obstruction of the common bile duct associated with long-standing jaundice. These latter are admittedly extremely poor surgical risks; they are on the verge of both hepatic and renal insufficiency, and in them nothing further should be attempted in the first instance than the relief of the biliary obstruction by the quickest and least disturbing procedure—a rapidly performed cholecystostomy (or choledochostomy if the cystic duct be obstructed)—no attempt being made to remove the calculi from the common duct until, as the result of free

drainage, all trace of “hepatic back pressure” has disappeared.

The comparative ease, safety, and success with which, nowadays, quiescent appendicectomy can be undertaken has led to its performance on a very large scale—often on very insufficient evidence that the appendix is the real cause of the symptoms complained of. I feel very strongly that the steadily increasing number of patients coming into our hospitals and nursing homes with chronic abdominal disease, upon whom a more or less recent appendicectomy has been performed without material relief to the symptoms, constitutes a very serious reproach to abdominal surgery. The appendicectomy *qua* appendicectomy has been skilfully performed, the wound has healed primarily, without complication, and yet, the symptoms not having been relieved, it is obvious that the appendix was not the cause of the trouble, or at any rate not the sole cause. The incision has usually been of the “gridiron” type, but sometimes Battle's or other variety of limited incision has been adopted. The fault lies in the fact that no general examination of the abdominal viscera was made during the operation, nor is such possible through any of these limited incisions; so far as non-urgent conditions are concerned “gridiron” appendicectomy is the curse of abdominal surgery, and there should be but one incision for this type—the “paramedian.” This reproach to our work will never be removed until surgeons generally come to regard every abdominal section for non-urgent conditions as essentially and primarily an exploratory laparotomy, however certain they may feel of their pre-operative diagnosis. It is the opportunity of a lifetime to discover the state, not only of the organs suspected, but of all the other abdominal and pelvic viscera; nor should the abdomen be closed until the surgeon knows the condition of every viscus it contains, at any rate so far as inspection or palpation can reveal it.

This routine examination should be thorough and carried out upon a systematic plan. A good rule, I consider, is to postpone the examination of the suspected viscus until the last, otherwise, should one's pre-operative diagnosis be immediately verified, there may be a tendency rather to scamp the rest of the systematic examination and so to overlook other concomitant, and possibly even more serious, lesions. It has happened to me on six occasions that, with a confident pre-operative diagnosis of chronic gastric ulcer, confirmed by radiography, this preliminary routine examination has disclosed an absolutely unsuspected early carcinoma of the bowel, a well marked gastric ulcer being also present in each case. The futility of treating surgically, however skilfully, a gastric ulcer and leaving behind a carcinoma needs no emphasis. It must be admitted that the prolongation of the operation necessary for this routine examination will slightly increase its risks, but I believe this to be more than counterbalanced by the advantage of not overlooking any other coexistent lesion. The general state of the patient must, of course, be considered, and where this is such that any prolongation whatever is considered unjustifiable, this routine examination should be omitted. In the majority of abdominal sections for non-urgent conditions, however, the general state of the patient is sufficiently good to permit of it, and, if otherwise, I believe it to be better practice to postpone operation for a while and attempt, by medical measures, to improve the general state rather than to operate at once and omit the routine examination.

CONCLUSION.

In concluding this review of the abdominal surgery of the last twenty-five years I feel very strongly that its progress has been such as successfully to stand comparison with that attained in any other branch of the arts and sciences—not even excepting the brilliant achievements of the “wireless.” So great has it been, in fact, that it seems difficult to believe that the next twenty-five years can continue this progress on quite such a dramatic scale. There are unquestionably plenty of problems connected with abdominal surgery still awaiting solution, but these are details of administration and of technique rather than the elucidation of great principles—the consolidation of positions already gained rather than the storming of new

"fortresses." One may almost say that there are no new "fortresses" left to storm, since all the abdominal viscera are now the subject of the surgeon's frequent attention; certainly there can be nothing in the next quarter of a century to compare with the victorious advance made during this in the treatment of acute abdominal crises by the general adoption of early operation.

Having personally witnessed this twenty-five years' progress, as I have, and glorying in it, as I do, I naturally decided to select this as the subject of my presidential address to you, and to illustrate it by reference to the statistics of the Manchester Royal Infirmary—an institution around which the whole of my professional life has revolved, and of which I am, we all are, intensely proud. And if I have failed to arouse in each one of you something of the profound faith and enthusiasm in the progress of abdominal surgery which I myself feel, then I must ask you to ascribe such failure, not to any inherent defect in the theme itself, but to the inadequacy of my descriptive powers to do even the most rudimentary justice to this truly wonderful chapter of surgical progress.

HODGKIN'S DISEASE IN MAN AND ANIMALS.*

BY

SIR HUMPHRY ROLLESTON, BART., K.C.B., M.D.,
REGENT PROFESSOR OF PHYSIC, UNIVERSITY OF CAMBRIDGE; PRESIDENT
OF THE ROYAL COLLEGE OF PHYSICIANS, LONDON.

Synonyms.—Hodgkin's lymphogranuloma, lymphadenoma, lymphogranulomatosis, or granulomatosis maligna.

Nomenclature has been a stumbling-block, for the terms "lymphosarcoma" (Virchow) and "pseudo-leukaemia" have been applied to what we understand by Hodgkin's disease, whereas quite a distinct and different significance now attaches to these two words. Cohnheim in 1865 employed the term "pseudo-leukaemia" to a condition in which the enlarged lymphatic glands showed the histological structure in leukaemia while the blood did not—in fact, to what would now be called aleukaemic leukaemia, the aleukaemic phase of leukaemia, or probably better aleukaemic lymphadenosis. Lymphadenoma, which in this country is synonymous with Hodgkin's disease, has the disadvantage that in America and France it is sometimes employed for what would be more accurately described as lymphadenosis, since it does not run the inevitably malignant course. Except for the drawback of the change it might be well to adopt the term, used for seventeen years by H. M. Turnbull, and also employed by Ewing, of "Hodgkin's lymphogranuloma."

Incidence.—As the nomenclature is a source of confusion, and the clinical diagnosis, especially from lymphosarcoma, difficult, the Registrar-General's returns may not settle whether the disease is becoming commoner, as some have thought, but they show an increase in the last ten years, from 280 deaths in 1913 to 371 in 1923.

Criterion of Hodgkin's Disease.

As the cause of Hodgkin's lymphogranuloma is unknown, it is necessary to fall back on its histological structure as the only means of defining exactly what is meant by the name; indeed, the diagnosis of a given case can be made with certainty only on its microscopic characters, for the clinical features and the response to treatment, especially to radiations, though strongly suggestive, cannot be regarded as final courts of appeal. The histological appearances, described independently and almost simultaneously by F. W. Andrews and Dorothy Reed in 1902, are so well known that it is unnecessary to do more than mention them—namely: (1) diffuse alteration of the structural architecture of the gland as a whole, showing (2) a diminished number of lymphocytes; (3) endothelial hyperplasia; (4) "lymphadenoma cells"; and (5) sometimes well marked eosinophilia. The blood changes are not patho-

gnomonic; there is often a leucopenia, especially in the earlier stages and in the cases of predominant splenic enlargement; when the disease is widespread a polymorphous nuclear leucocytosis is common, and in rare instances there is a well marked eosinophilia, the significance of which is not clear.

Valuable as microscopic examination of an excised gland is, biopsies are not free from fallacies, for although there is lymphadenoma elsewhere the gland excised may show nothing more than indefinite lymphoid hyperplasia due to simple inflammation or compensatory for the destruction of other lymphatic glands. But Webster found that biopsies gave more positive results in Hodgkin's disease than in cases ultimately proved to be lymphosarcoma.

Nature of Hodgkin's Disease.

Lymphadenoma has been thought to be (1) a neoplasm, (2) a transition between a neoplasm and an inflammatory formation, and (3) as seems most probable, an infective granuloma, though the responsible virus, in spite of the descriptions of the tubercle bacillus (C. Sternberg; Frankel and Much), a Gram-positive pleomorphic diphtheroid bacillus (Bunting and Yates), and a spirochaete (White and Proecher), has not yet been established.

The view that Hodgkin's disease is a neoplasm rests on several considerations, and perhaps chiefly on the assumption that in its early stage it is confined to existing lymphadenoid tissues, and that later it generalizes like sarcoma and invades tissues, such as muscle and bone, which do not contain any lymphoid tissue; this generalization, however, is quite compatible with the characters of the infective granulomas. The second reason is that in the late stages the histological characters may become those of a sarcoma—"Hodgkin's sarcoma," as Ewing (1922) calls it. If and how often this sequence has been actually proved by biopsy and necropsy I do not know; it is said by Ewing to occur often in mediastinal lymphadenoma, but these are just the cases in which a biopsy may be impracticable. Now the various kinds of cells seen in the early stage are much more like the inflammatory changes in the infective granulomas than the structure of a sarcoma, even though a mixed-celled. But Mallory groups together under the term "lymphoblastoma," as true tumours, Hodgkin's disease, lymphoid leukaemia, and lymphocytoma. It is a rather different and difficult question whether Hodgkin's lymphogranuloma becomes transformed during its course into Hodgkin's sarcoma, or whether the condition is sarcomatous from the start and becomes more virulent with the progressive impairment of the patient's resistance. On the analogy of chronic irritation as an antecedent of carcinoma and of the rare occurrence of sarcoma and carcinoma in the same growth, it would be reasonable to believe that a gland originally the site of chronic inflammation may later become sarcomatous, and Ewing (1913) has observed this sequence of events in cases in which repeated operations have shown the elimination of the original granulomatous lesion. But it would appear to be an open question whether the sarcomatous change occurs in the cells of Hodgkin's lymphogranuloma or in the tissues around, the latter process being analogous to the occurrence of a squamous-celled carcinoma in the site of cutaneous lupus.

Situation of the Disease.

The primary site of lymphadenoma is usually regarded as the cervical glands, as shown by the statement that these are first affected in from 50 (Ziegler) to 75 per cent. (Bunting) of the cases. But it does not follow that the glands first palpably enlarged are necessarily those first attacked; on the rather slender basis of fourteen cases Symmers has insisted that primary enlargement starts in the abdominal or in the abdominal and thoracic glands ten times more often than in the cervical, and Ewing confirms this. Its starting-point after that of practical importance as determining not permit me this area to be treated by x rays or radium. The marked advances that of Hodgkin's disease is that just twenty-five years in the to is in the lymphadenoid masses, of the intestines, and more keen, the mesenteric and but were I to do so it would be but, it very rarely attacks same tale of steadily continued progress

* An opening paper of a joint discussion of the Sections of Medicine and Comparative Medicine at the Royal Society of Medicine on January 26th, 1926.

the lymphoid tissue of the alimentary canal. It is true that cases, such as G. N. Pitt's collection of twenty-five cases, have been described, but it is significant how few have been recorded since 1902, when the histological characters were established.

Satisfactory evidence that Hodgkin's disease has ever been transmitted to animals is wanting; Bunting and Yates, after repeated injections of their diphtheroid bacillus isolated from lymphadenomatous glands, obtained appearances in five *Macacus rhesus* monkeys resembling "the early changes of Hodgkin's disease as seen in man"; but this is rather ambiguous, for the lymphocytic hyperplasia which Bunting describes in the early stage of Hodgkin's disease resembles inflammation. Other observers have failed to confirm this. Inoculations of material from lymphadenomatous glands into monkeys have given negative results (Longcope; Cunningham and McAlpine; Stewart and Dobson). Stewart and Dobson described "a peculiar giant-celled reaction, probably of foreign body type, around the implanted material," which is of some significance in relation to the early changes of lymphadenoma reported by Bunting and Yates. C. C. Twort found that guinea-pigs frequently reacted to inoculation of pieces of lymphadenomatous tissue by the production of transient local nodules which histologically were entirely of an inflammatory nature.

HODGKIN'S DISEASE IN ANIMALS.

The chief interest of to-night's discussion, at which we welcome our colleagues of the Section of Comparative Medicine, is the question of the occurrence in animals of Hodgkin's disease as established by the histological appearances now accepted as characteristic in man. It is described as occurring in the so-called lower animals, but how far is this based on clinical rather than on microscopic evidence either by a biopsy or necropsy? In 1903 John McFadyean, under the title "Five cases of Hodgkin's disease in the lower animals," quotes F. W. Andrewes's account of the histological picture, and adds: "If the characters above mentioned are essential to Hodgkin's disease or lymphadenoma, the cases which I am about to describe have no title to be called by these names." This frank admission applies to nearly all the few recorded cases of lymphadenoma in animals that I have come across, which might more safely be headed lymphoma; thus in Hodgson's brief account of "Hodgkin's disease in a pig" the glands microscopically "showed simply an excess of lymphocytes above their normal structure." In G. Simons's case of Hodgkin's disease in an Aberdeen terrier there was no *post-mortem* examination; in Reed's case of Hodgkin's disease in a horse the microscopic appearances of the glands were "a hyperplasia of the cellular elements and an increase in the gland stroma." Hobday's case in a dog, however, was examined after death by Sir John McFadyean, who is quoted as stating that "it was a typical case" without any further details. There does not appear to be any reason why Hodgkin's lymphogranuloma should not occur in animals, but more information is required about the microscopic appearances of cases so diagnosed on clinical grounds.

DIAGNOSIS.

The greatest difficulty in the differential diagnosis of Hodgkin's disease is the clinical differentiation from the variously named primary sarcomas of lymphoid tissue—lymphosarcoma, malignant lymphocytoma, endothelioma. In many cases this can only be done by microscopic examination of an excised gland.

Cases of secondary malignant growth in the cervical and supraclavicular glands may imitate Hodgkin's disease when the primary growth in the mediastinum, or even the oesophagus, is latent and the chest is not skigraphed. I have seen a case which, after imitating Hodgkin's disease, became one of cancer en cuirasse, so that a small primary carcinoma of the mamma probably escaped detection. I have twice seen the following condition suggest Hodgkin's disease: a primary malignant hypernephroma of the left adrenal or kidney producing a tumour, taken for an enlarged spleen, and secondary glands above the left clavicle.

There are certainly a number of chronic enlargements of a hyperplastic or inflammatory character, though of undetermined origin, which clinically are regarded as Hodgkin's disease, and in which the doubt about the diagnosis only arises when a biopsy or necropsy upsets the clinical opinion. These may be toxic or probably due to a low-grade infection. Ledingham found that the virus of vaccinia, and possibly of small-pox, may set up changes in the cells of the reticulo-endothelial system resulting in an acute granuloma. In chronic infection of the urinary tract by *B. coli* I have seen glandular enlargement suggesting Hodgkin's disease. Brill, Baehr, and Rosenthal described splenomegalia lymphatica hyperplastica, a condition showing generalized and gigantic hyperplasia of the lymph follicles of the lymphatic glands and of the Malpighian bodies in the spleen: the blood count was normal, and the condition was rapidly cured by x rays; but before this was found out splenectomy was performed in two cases (one followed by death). Cases described as infectious mononucleosis and glandular fever run a short course, and so are not likely to give rise to much difficulty in diagnosis.

Tuberculous adenitis may come before us in three forms in connexion with the clinical diagnosis from lymphadenoma; the first is common and often commonplace, the second very rare, and the third so exceptional as to have aroused some scepticism (F. P. Weber; Lyon; Sprunt). (1) Tuberculous glands in the neck often simulate lymphadenoma, especially when the glands show tuberculous large-celled hyperplasia without necrosis or caseation. (2) Generalized tuberculous adenitis may, as MacNalty showed, be accompanied by the relapsing fever described in lymphadenoma by Murchison (1870), Pel (1885), Ebstein (1887), and often, regardless of strict priority, called the Pel-Ebstein syndrome, for Morgagni in 1769 briefly recorded an example. This generalized tuberculous adenitis, when it occurs, may be associated with visceral infection—for example, of the lungs (MacNalty)—though the absence of splenic enlargement, which occurs in about 75 per cent. of generalized lymphadenoma, is of some diagnostic value. In very rare instances, of which Crip and Narr could not find more than a very few recorded cases, the infection appears to be confined to the glands; in their patient and in another recovery occurred. (3) The condition, little if at all accepted in this country, described as adeno-lipomatosis, in which fatty growth occurs around lymphatic glands which may be tuberculous, a process regarded as an effort to localize the disease. In fat persons in the early stage of lymphadenoma the question of diagnosis from adeno-lipomatosis has arisen, at any rate in my mind.

INFANTILE PARALYSIS.

A CLINICAL STUDY.

BY

J. M. GILL, M.D. LOND.,

PHYSICIAN TO THE SYDNEY HOSPITAL AND TO THE ROYAL ALEXANDRA
HOSPITAL FOR CHILDREN, SYDNEY, N.S.W.

THERE have been many epidemics of infantile paralysis in Australia and New Zealand during the present century. The first occurred in Sydney in 1903, during November and December, when about forty cases were treated at the Children's Hospital. From Sydney it spread during the course of the following year over the greater part of New South Wales and Queensland. From 1903 to 1909 there was an interval, but from 1909 to 1916 there were annual epidemics, always reaching their height in the later half of the summer and in the autumn. There was again an interval till 1921. There were mild epidemics in Sydney in 1921, 1923, and 1924, but none this year (1925). In 1923 I collected the notes of about ten or twelve cases altogether, some being doubtful. In 1923 there were forty cases in the hospital, seventeen being under my care; one doubtful case was fatal, but no *post-mortem* examination was allowed. In 1924 there were forty-five cases in the hospital, one fatal; no *post-mortem* examination was allowed. The last two epidemics were very similar. They both reached their maximum later than usual. In 1923 most cases were admitted in May, a cool month; in 1924 in March. Both epidemics were mild, with a high recovery and a low mortality rate. A very extensive epidemic visited New Zealand, but not Australia, in 1925.

Age.—Of forty cases in the Children's Hospital in 1923, eighteen were between 1 and 2 years of age, and twelve between 2 and 3 years; that is, thirty out of forty were in the second and third years of life. There was only one under 12 months (7 months); the oldest was 8 years of age. The age incidence in the 1924 epidemic was very similar. These figures agree with those published by other writers. In Sydney cases in adults have been very rare, and the disease is very seldom seen even in adolescent boys and girls.

Most authors follow Wickman and describe eight clinical types. These are usually given as follows:

1. Spinal or common type.
2. Landry's paralysis type.
3. Bulbar or pontine.
4. Encephalitic type, which is responsible for many of the fatal cases in infants.
5. Neuritic type. There is some doubt about this forming a separate group, as neuritic symptoms are very common in the spinal form. Speaking for myself, I have never seen a case in which the central nervous system was not involved.
6. Meningitic form.
7. Transverse myelitis type.
8. Abortive form.

The classification into types is convenient, as the symptoms vary a good deal in different cases.

CASE I.—*Rigidity of Spine with Paralysis of Legs.*

I shall begin by describing a typical case in the Children's Hospital last year (1924). She had been treated at the outdoor department for about a week before admission. She was 1 year and 10 months old, well nourished and healthy-looking. She cried as the cot was approached, and evidently found the process of undressing preparatory to examination very disagreeable. On placing the hand behind her head, the neck was found to be stiff and the child cried with pain. On raising her from the bed the whole spinal column was found to be rigid, and the child fell quite helplessly back when her hand was removed. Both legs were paralysed, one more than the other; both knee-jerks were absent. When the muscles were all flaccid and not tender on handling, the paralysis appeared to be perfectly normal in every way. The arms which would usually be

We have here a typical case, which the disease affecting the motor cells of the legs, due to a neurone lesion. The rigidity of the neck and trunk, which is usually much engorged and infiltrated with leucocytes—that is, Wickman's Type 6.

3. Paralysis of the neck and trunk, which rendered the child quite unable to maintain herself in the sitting posture, was due to a general involvement of the motor cells in the spinal cord.

This kind of case is the most common and ends in complete recovery except for some of the muscles of the legs.

CASE II.—*Rigidity of Legs.*

A child, aged 2½ years, had rigidity of the neck and spine, and paralysis of the muscles of the trunk, but with the legs rigid and stiff in the extended position. The knee-jerks were exaggerated. This case differs from the other, only because the lumbar enlargement has escaped injury. It corresponds to the meningitic type of Wickman.

CASE III.—*Rigidity and Flaccidity of the Legs.*

A child, aged 2 years, presented a combination of the symptoms of the previous two: some of the muscles of the legs were rigid, while others were flaccid. One leg was kept stiff with the knee extended, and the knee-jerk was exaggerated; the other was quite flaccid and helpless, and the knee-jerk was absent.

This last type is quite common, although not so common as the first case. Rigidity of the legs quickly disappears, generally in a week or two, leaving the limbs more or less completely paralysed. Probably rather less than half of all cases show rigidity; though in some it may have been present before admission. Wickman called attention to this condition and recognized its cerebral origin; he suggested that it was caused by the spread of the inflammatory process from the anterior cornua to the lateral columns, thereby leading to a condition similar to lateral sclerosis. The rigidity of the trunk does not disappear so rapidly as that of the legs, and stiffness of the neck last of all. Paralysis of the trunk and neck remains long after all stiffness has disappeared—that is, the child is unable to raise itself into the sitting posture in bed and unable to maintain itself in that position even when placed in it. These three types constituted the vast majority of all cases in our last two epidemics. There were indeed some mild cases, which showed no rigidity, but yet had paralysis of the trunk. I give the notes of one such child under my own care.

CASE IV.

A boy, aged 4 years, was admitted on April 19th, 1921, with a history of a week's illness; the onset was said to be sudden with paralysis of both legs and inability to walk. When examined on April 20th he had fair power in the legs and no anaesthesia. He could not sit up in bed or stand. There was no head retraction or other stiffness. The knee-jerks were absent. The legs moved freely when tested with a pin prick. On April 25th he could sit up; the knee-jerks were still absent. On May 2nd he could sit up well; the knee-jerks were still absent. Three days later he could sit up quite well, but could not stand; the knee-jerks were present, but difficult to get. By May 16th he was improving, and could stand with assistance. He was discharged, well, on June 2nd. The temperature was normal throughout.

In this mild case paralysis of the trunk was the most prominent symptom; the legs were only slightly affected and the arms not at all. Such cases, though, without rigidity are rare.

CASE V.

In this case, a girl aged 1 year and 10 months, the onset was quite sudden. She was quite well on March 27th at 11 a.m. She was suddenly seized with paralysis and was admitted to hospital the following day, when it was found that she was unable to stand or sit up. The legs were flaccid, but the knee-jerks were present. There was some difficulty in micturition and defaecation, which, however, quickly disappeared. Recovery was rapid and continuous. She was discharged on June 1st, having made a complete recovery.

This case is of interest because the mother was able to state almost to a minute when the paralysis set in. It suggested at the time that there was a vascular lesion. It is difficult to conceive a diffuse lesion of the spinal cord arising in this way. The different symptoms shown by the cases quoted will now be discussed.

Rigidity of the Neck.

Rigidity of the neck is a very common symptom in infantile paralysis; it is present in 80 per cent. of all cases, according to Foster. I have not endeavoured to work out the percentage in our cases, as many are not admitted till after all acute symptoms have subsided. It is probably entirely absent in a few only. It varies a great deal in severity from day to day and from case to case. Retraction may be so marked that the child can only lie on its side. In mild cases it may be necessary to flex the patient's neck

to bring rigidity out. The muscles all round the neck, back and front, are stiff. Usually great pain is caused by any attempt to flex the neck. It may be very variable from day to day; it may even be very stiff one day and quite relaxed the next. The mistake should not be made that it is voluntary on the part of the child.

Rigidity of the neck in infantile paralysis is precisely similar to that of the common forms of meningitis in childhood, but the extreme degree of retraction sometimes seen in the pneumococcal or posterior basic form, in which the occiput may almost touch the buttock, does not occur.

It is important to realize that this symptom is not necessarily due to meningitis, although it is often the most prominent sign. In cerebro-spinal meningitis it is of course usually very well marked, as also in the posterior basic form described by Barlow and Lees. In tuberculous meningitis it is only occasionally present, is never early, is less intense, and is much less persistent. In pneumococcal meningitis it is sometimes present and well marked. All writers remark on the frequency with which it appears in meningitis of the posterior fossa. It may also appear as the result of otitis media, disappearing as the ear gets well. But it is frequently present when there is no meningitis at all, as in pneumonia. In severe cases of gastro-enteritis it may be very marked, again without any sign of meningitis, and often ends in complete recovery. In pneumonia it does not seem to add to the gravity of the prognosis, and does not usually last more than two or three days. The absence of actual pneumococcal meningitis can be established by lumbar puncture. I have seen it also in a case of cerebellar tumour. At the post-mortem examination a tumour was found in the left lobe of the cerebellum, but no meningitis. This child was aged 2 years, and during life had been looked upon as an example of the chronic form of cerebro-spinal meningitis, owing to the marked retraction of the head and rigidity of the spine and legs. Though rare in typhoid fever, it may occur, leading to the well known clinical resemblance between this fever and meningitis. Almost any toxic condition in a small child can lead to it. For instance, a child was admitted to hospital with a retraction of the head due to a sinus in the buttock. The sinus healed after a few days' treatment, and the retraction of the head disappeared at the same time. It is therefore certain that rigidity of the neck, trunk, and legs may appear in children as the result of a great variety of infections without meningitis, and also from cerebellar tumour.

It has been suggested that retraction of the head is due to increased fluid collecting in the cerebello-pontine angle. This explanation cannot apply to infantile paralysis, as the rigidity of the spine and legs must be explained also. I believe that it is generally supposed that in meningitis of the posterior fossa irritation of the first three cervical nerves, direct or reflex, leads to head retraction. This explanation is inadequate for two reasons: it does not account for the cases where there is no meningitis, and it does not take into account the effect of meningitis on the cranial nerves in the posterior fossa. If there be irritation of the cervical nerves, should there not be also irritation of the cranial nerves? Spasm of any of the muscles supplied by the facial and other nerves traversing the posterior fossa is unknown in meningitis and the other conditions described above. The supposition that rigidity of the neck is due to "irritation" may therefore be dismissed.

Rigidity of the spine frequently accompanies retraction of the neck in infantile paralysis, though not always. When it is present it clears up before the latter. It is often present in meningitis. It is evidently similar in nature and origin to retraction of the neck, the same causes leading to each. It is obvious, of course, that "irritation" is an inadequate explanation, since the extensors of the trunk alone are involved in the spasm, the flexors escaping altogether, as well as the muscles of the arms, and frequently those of the legs. The abdominal muscles always escape.

The rigidity of the legs has already been mentioned. In my experience, the legs are always kept in the extended position. The spastic condition never lasts long, disappearing before that of the trunk. It is clearly of cerebral origin, although it is doubtful whether Wickman's sugges-

tion that it is due to involvement of the lateral columns by the inflammatory process is the true one.

Any satisfactory explanation of these phenomena must apply to all three, since the same characters belong to each. In each certain muscles only are spastic—namely, those which maintain the trunk and limb in the extended position; the muscles of the upper limbs remain free, as well as the abdominal muscles. The spasm may be maintained for days and weeks. Now these are the attributes of contracting muscles, subserving "posture," as pointed out by Sherrington; the "lengthening and shortening" reactions are difficult to demonstrate, as the muscles are too tender as a rule to admit of much manipulation. But there is no doubt that the attitude of a child with infantile paralysis may be very similar to that of the decerebrate animal, dog or cat, described by Sherrington, with the significant exception that the arms of the child are not rigid, like the forelegs of the animal, which are used for standing. As Sherrington puts it, the position is one of reflex standing. Following Hughlings Jackson, one may attribute the rigidity to loss of cerebral control. Warner and Olmsted have lately described a tract, proceeding from the cortex of the frontal lobe, capable of inhibiting decerebrate rigidity, as postulated by Hughlings Jackson. One is naturally tempted to think that this tract may be injured in some part of its course. Decerebrate rigidity may also be inhibited by electrical stimulation of the vermis of the cerebellum, as Sherrington and others have pointed out. There is nothing in the clinical aspect of rigidity to lead one to a definite conclusion as to how inhibition may be brought about in the human being. It is clear, however, that in infantile paralysis we sometimes have a clinical condition strictly comparable to the "decerebrate rigidity" described by Sherrington, as occurring in a cat, the section passing posterior to the mid-brain, but leaving the pons and cerebellum intact.

Retraction of the neck is not so often seen in the adult as in the child, and when present is usually less marked. Tumours and abscesses in the cerebellum, haemorrhage into the posterior fossa, and meningitis just about exhaust the list. The neck is generally rigid rather than retracted. In a boy aged 15 retraction of the neck was the most marked symptom. In the adult pneumonia is never associated with rigidity of the neck, so far as I know, nor are any of the other toxic conditions already mentioned. The question arises, then, Why should retraction and rigidity of the neck occur so frequently in childhood in a variety of diseases in which it is never present in the adult? No satisfactory answer to this question has been given. The rigidity of the adult presents exactly the same attributes as that of the child; it is certain that a similar mechanism is involved in each. It is reasonable to suppose that in the child rigidity, being a more primitive (a lower level) function, is less completely inhibited than in the adult. In other words, it is a "release" phenomenon, in Hughlings Jackson's sense.

Paralysis of the Trunk.

Paralysis of the trunk usually occurs side by side with rigidity. Rigidity may be absent in exceptional cases as already mentioned. In most cases in which rigidity and paralysis of the trunk are combined rigidity clears up before the paralysis. Generally speaking, rigidity disappears in a week or two, or a month at most, while the trunk still remains paralysed. A child, aged 17 months, under treatment in 1923, admitted with paralysis of the trunk and rigidity of the neck and trunk, did not recover the power of sitting up in bed for seven and a half weeks. During the whole of this time she lay on her back in bed quite helpless, unable even to turn in bed; there was no paralysis of the legs or arms, but the knee-jerks were exaggerated. Complete recovery took place without wasting of any of the muscles.

A lesion of the lower motor neurone is not infrequently absent, but at the age at which infantile paralysis is common paralysis of the trunk is the most characteristic symptom. It is demonstrated by putting the child on its back in bed, placing the hand behind the shoulders and raising them from the horizontal to the sitting-up position. If there be rigidity, the head, neck, and trunk may be held

in one almost straight line; but still the child is absolutely helpless. This symptom does not, I think, occur in other diseases than infantile paralysis in early childhood. I noticed, for instance, in a case of pneumococcal meningitis, that the child was able to raise herself in bed without any special difficulty, although her neck and back were quite stiff. This child appeared to be recovering, but died soon after.

This paralysis of the trunk is too obvious a symptom to have escaped notice before. Many writers mention it, but do not attach any special importance to it, evidently looking upon it as one of the many manifestations of the lesion of the lower motor neurone. There are two sufficient reasons for rejecting this view. (1) Any subsequent wasting of the muscles of the trunk is unusual. Complete recovery is the rule, although it may take some weeks, as in the case already quoted. This is in striking contrast to the paralysis of the legs, in which complete recovery is the exception. In the last two epidemics, which have formed the principal basis of this paper, only one case of residual paralysis of the muscles of the neck or trunk was observed. This child recovered completely from the paralysis of the trunk after about two months, but paralysis of the muscles of the neck remained with wasting. A mechanical contrivance had to be devised to hold her head up. In this case it was clear that the motor cells in the upper cervical portion of the cord had been destroyed. Permanent paralysis of the muscles of the upper extremity, also rare. (2) Usually the muscles of the upper extremity, and occasionally those of the upper limb, escape paralysis altogether. It is impossible to suppose that such a widespread and destructive lesion could involve the thoracic and cervical portions of the spinal cord and leave out the cervical and lumbar enlargements.

There must be some connexion between this paralysis of the trunk and the rigidity previously described. They have much the same muscular distribution and are generally associated with one another. It is natural to suppose that the cerebellum is the organ involved. Usually the child can carry out all voluntary movements other than those involved in the assumption of the erect posture. The child can talk, feed itself, and otherwise use the hands as well as ever. It can move the legs in bed, lift them up, and carry out any ordinary muscular movement; but yet cannot use the legs for standing. It is clear that we have here no ordinary form of muscular paralysis, due to disease of the lower motor neurone. The incidence of the paralysis shows clearly that it must be of cerebral origin. It cannot be due to disease of the cerebral cortex, as all ordinary voluntary movements can be readily carried out, apart from those of the trunk. "Atonia" has been regarded as a result of disease of the cerebellum for many years. It is clear that in infantile paralysis the function of standing is lost for a time. This function is almost automatic. It is also exceedingly interesting that rigidity of the neck and trunk should be so often combined with paralysis of the trunk in infantile paralysis, and yet be dissociated from it in other cases; also that in some cases of meningitis rigidity should exist without any real paralysis of the trunk. The explanation would seem to be that in meningitis the cortex alone is injured, while in infantile paralysis the cerebellum is injured in addition.

The question arises, Why are these two symptoms, rigidity and paralysis, so common at this early age, whether the case be one of infantile paralysis, meningitis, pneumonia, gastro-enteritis, or other form of toxæmia? I think that one of Hughlings Jackson's axioms may be the answer to this question—namely, that the most recently acquired function is the first to be lost in disease of the nervous system. The most important functions a child acquires during the first two years of life are those of standing and walking. Few things are more striking in the newborn infant than the total want of tone in the muscles of the neck and of the arms, but it has no control whatever over the muscles of the neck. It is not till after about three months that the child is able to hold the head up; at about 12 months of age it should be able to stand and perhaps to walk. This process is very slow and gradual; even when acquired, the child is for a

long time very unstable in standing, running, or walking. It seems reasonable to suppose that this function is particularly vulnerable in the second and third years of life when infantile paralysis is common. No doubt the cerebellum is the organ which controls it. The cerebellum exercises, in conjunction with the medullary and pontine nuclei, a tonic influence on the muscles of the trunk especially, and on those of the legs to a less degree, which makes the assumption of the erect posture possible. In infantile paralysis the power of assuming the erect posture is lost altogether for a time in many cases.

Landry's Paralysis and other Types.

The acute ascending type, which is often fatal and which resembles the form of paralysis described by Landry in 1859, has not formed a feature of recent epidemics in Sydney. It usually occurs in older children, and includes most of the fatal cases in some epidemics. It seems likely that further investigation along the lines here set forth might give useful results. The cerebral type is very apt to be mistaken for meningitis; there may be rigidity of the neck with convulsions, as in one of my cases. A child, aged 1 year and 11 months, was admitted in general convulsions in March, 1909; the convulsions next day were limited to the left half of the body. The left half of the body was paralysed. She was subject to fits of the Jacksonian type for some ten years, and then she passed from my observation. The cerebral cortex was no doubt the chief seat of disease in this child. Is it too much to assume that the cerebellar cortex was also affected?

I did not intend in this paper to deal with the subject of rigidity in anything like a comprehensive way, but merely to discuss one aspect of it. The work of the late Professor Hunter has directed the attention of the profession to the whole question, in a most lucid and masterly fashion. Almost all the observations given in this paper were carried out before his work was published. The issues of the *BRITISH MEDICAL JOURNAL* of January 31st, February 7th, 14th, 21st, and 28th, 1925, which contain references to recent researches bearing on the subject, should be consulted for a full description of Hunter's work.

THE ACTION OF PITUITARY EXTRACT ADMINISTERED BY THE ALIMENTARY CANAL.

BY

H. H. KNAUS, M.D.,

ASSISTANT AT THE UNIVERSITY CLINIC FOR GYNAECOLOGY AND OBSTETRICS, GRAZ; ROCKEFELLER FELLOW.
(From the Pharmacology Department, Cambridge.)

SINCE von den Velden¹ first showed the specific action of pituitary extract in cases of diabetes insipidus this drug has been used very widely by clinicians, and has proved a helpful remedy, not only in diabetes insipidus, but also in surgical shock, and especially for its action on the uterus. This widespread use of pituitary extract has naturally led to administration by various methods. It has been recognized generally that pituitary, when given intravenously, subcutaneously, or intramuscularly, shows a distinct influence on all those organs on which it is known to act. The effect of pituitary after any method of injection is, however, limited to a comparatively short time, and repeated injections are required in order to keep the patient under the influence of the drug. In cases where repeated injections have been tried, but there has been no unanimity as to the results. Kennaway² and Blumgart,³ Barker and Mosenhall,⁴ report that they have never observed any pituitary action after administration by the mouth. Wolpe,⁵ Hamill,⁶ and Donaldson,⁷ on the other hand, observed a distinct action after oral administration. Abel and Gisling,¹⁰ Rowntree, and Blumgart have produced evidence of the successful application of pituitary by the nose, and finally Rosenfeld¹¹ may be mentioned for having observed a slight effect after rectal administration. All these observations have been made clinically on patients suffering from diabetes insipidus or from uterine haemorrhage, except Hamill's investigation, which was carried out

on cats. As the literature up to date does not give any clear evidence of the pituitary action on blood pressure and uterine movements after administration through the different parts of the alimentary canal, an accurate study of this subject appeared to be desirable.

In the investigation here described cats were used; they were anaesthetized with chloralose and the blood pressure was registered from the carotid artery. The uterine movements were recorded in the following way. The abdomen was cut open in the mid-line just above the urinary bladder. A small incision was then made in the vaginal wall as near the vulva as possible. A glass tube was inserted and tied into the vagina and the uterus was then filled with liquid paraffin. The vaginal glass tube was connected by rubber tubing with a manometer in order to regulate the pressure, and the rise and fall of the oil caused by uterine contractions were recorded by means of a tambour. The pressure naturally varied according to the size and condition of the uterus, but on an average was about 10 cm. This method was very successful, as the abdomen could be kept closed, trifling movements of the animal did not affect the record, and an accurate investigation could be continued for a prolonged time. All experiments were completed by an intravenous injection

The results obtained by using the methods described above are more or less in accordance with the bulk of observations made by clinicians. Clinical observations of this kind are by the nature of things extremely difficult to interpret, as they lack the necessary controls.

So far as Wolpe's and Donaldson's observations are concerned, the authors may probably be right in stating that pituitary extract acts when given by the mouth, but the important fact to appreciate is that the absorption of the active principle takes place in the mouth and not in the stomach. Hamill's observation that strong uterine action is produced by pituitary extract when introduced into the stomach is based on experiments which are open to many criticisms. The method of recording uterine movements was such that any small movements of the animal upset the record, and in a long experiment this is a very important point. Hamill does not appear to have employed curare to counteract this. He states himself that the records were difficult to obtain on account of peristalsis and straining. My own experience is that the method employed by Hamill is not valid for this type of experiment on account of the difficulty in interpreting the results. My own experiments point to the fact that no pituitary action whatever occurs when the drug is intro-

FIG. 1.—Cat, weight 3 kilos, uterus big and relaxed; at the arrow 1 c.cm. of pituitrin was administered by the mouth.

of pituitary extract in order to test the reliability of the method. The pituitary extract used was that of Parke, Davis and Co., and my thanks are due to this firm for the free supply of the drug.

1. Action when given by the Mouth.

The oesophagus was tied at its entrance into the chest, and the pituitary extract was then placed under the tongue, this being considered the best place for absorption. The tracing (Fig. 1) shows quite distinctly the powerful action on the uterine muscle, and the complete lack of any simultaneous pressor effect. This experiment, which may be regarded as typical, shows quite clearly that pituitary extract is not only absorbed by the mouth, but that the absorption was remarkably rapid in the instance illustrated, a marked effect being obtained in eight minutes.

2. Inaction when given by the Stomach.

In these observations care was taken to avoid any absorption in the mouth. The pituitary extract (1 to 2 c.cm.) was introduced directly into the stomach by means of an elastic catheter. As a result of repeated experiments it is certain that under the conditions stated no effect is produced, either on the blood pressure or on the uterine muscle after administration by the stomach. A subsequent intravenous injection of an appropriate amount of pituitary extract given at the close of the experiment has always shown its typical effect.

3. Inaction when given by the Small Intestine.

In order to introduce pituitary extract directly into the small intestine a small incision was made in the mid-line of the abdominal wall and a short loop of the jejunum exposed. This exposure was always followed by a marked rise of blood pressure, and thus it was necessary to wait a certain time until the animal came back to normal conditions before giving the pituitary extract. When the blood pressure had regained its normal level 1 to 2 c.cm. of pituitary extract was injected into the jejunum by means of a very fine needle attached to a syringe, and immediately afterwards the exposed loop was replaced and the cut in the abdominal wall closed. The result of these experiments was in all cases the same as those obtained after the pituitary was introduced into the stomach—namely, that no action whatever, either on the blood pressure or on the uterus, was obtained.

4. Action when given by the Rectum.

These experiments were made under conditions identical with those already described: 1 to 2 c.cm. of pituitary extract was introduced into the rectum by means of an elastic catheter attached to a syringe. These experiments have shown quite clearly that pituitary extract produces a distinct but slight effect on the uterine muscle, but has no action on the blood pressure. The effect is first seen about fourteen minutes after administration.

duced into the stomach or small intestine in reasonable amounts.

Furthermore, it seems to me important to draw attention to the fact that pituitary extract, when absorbed from the mouth or rectum, produces only the uterine effect. I have shown elsewhere¹² that there is every evidence of the existence of two distinct principles in the pituitary body—namely, the oxytocic and the pressor substances, the latter of which is very easily destroyed by passing through capillaries. The investigation here reported affords further proof of that assumption, for the remarkable change of the uterine movements proves the absorption of the oxytocic principle, while the absence of effect on the blood pressure proves the non-absorption or immediate destruction of the pressor substance.

Summary.

1. When pituitary extract is administered at any part of the alimentary canal—mouth, stomach, small intestine, rectum—pressor action is never observed.

2. When pituitary extract is introduced into the stomach or small intestine it exerts no influence on uterine muscle.

3. When pituitary extract is administered by the mouth, after a latent period of about eight minutes it exerts a marked action on the uterus, increasing both the tone and automatic movements. The oxytocic substance is therefore absorbed. The rectum absorbs the oxytocic substance also, although the absorption is probably not so complete.

My sincere thanks are due to Dr. W. E. Dixon, F.R.S., for his kind help and criticism during the course of these experiments.

APPENDICOSTOMY FOR THE RELIEF OF THIRST AND INANITION AFTER ABDOMINAL OPERATIONS.

BY

H. DE LISLE CRAWFORD, M.D., M.Ch., F.R.C.S.I.,
WALLASEY.

In the surgery of the digestive tract post-operative treatment is of great importance throughout the first week. A patient who has suffered for months from malnutrition due to ulceration or gall stones comes to operation in a cachectic and emaciated condition, the operation perhaps made urgently necessary by perforation or pain. Such a patient, lacking reserves, is unable to stand the semi-starvation which follows, and may die within three or four days from thirst or starvation. The stomach will not retain enough fluid. The rectum returns it. Blood transfusion and intravenous infusions of various kinds are useful for the moment, but their effect is transitory.

Jejunostomy jeopardizes a most vulnerable and important part of the gut, and appendicostomy has hitherto entailed a gridiron or other secondary incision.

I wish now to describe a method by which appendicostomy may be performed in a few seconds at the close of any ordinary abdominal operation by means of a stab incision.

Method.

1. At the end of the main operation the appendix is palpated and freed from any lateral attachments so that it is supported by the mesentery alone.
2. A small scalpel is placed on the middle finger and palm of the left hand and inserted into the abdomen. The tip of the middle finger is applied to the inside of the right abdominal wall about 2 inches internal to the right anterior superior iliac spine at the level of the appendix base. The knife is then pushed through the wall forwards and slightly outwards by flexing the wrist and hand.
3. The knife blade is gripped by a small artery forceps and then pulled back into the abdomen, carrying with it the jaws of the forceps.
4. The knife is removed from the jaws of the forceps and the tip of the appendix is substituted for it. The forceps is then pulled out, followed by the appendix. It is important not to twist the appendix, and palpation of the meso-appendix will determine whether or no this has happened. I have found that most of the appendix comes out without severe pulling, and there is apparently no need to be afraid of using some force.
5. The mesentery is ligatured a quarter of an inch outside the skin and two sutures of silkworm-gut are passed through the skin and appendix wall to anchor the latter.
6. Finally, after closing the main abdominal wound, the appendix is cut off half an inch from the skin. A small catheter is introduced for several inches and tied in. The dressing is arranged so that the catheter comes through and is controlled by a clip.

Before leaving the table one pint of saline and glucose is run in through a funnel, and this is repeated hour after hour as long as may be necessary. Usually when conscious the patient resents the introduction of a whole pint at a time, and the best direction to the nurse is that she pour in the fluid at regular intervals until the patient complains.

I used this method first in 1912 in a case of perforated gastric ulcer. Seventeen pints were given in the first seventeen hours, and as the pulse had then fallen from 144 to 70 there was no need to continue. This patient did not ask for any drink by the mouth.

Since then I have used it in nine cases, of which only one has died. This was a gas infection of the liver due to gunshot wound in France. He died two weeks after operation.

My last case was an emaciated woman, aged 39, with hour-glass stomach, upon whom I performed hemigastrectomy. She vomited small amounts for two days, in spite of which her pulse fell from 100 to 72 in the first six hours and to 60 by the eighteenth hour. She did not complain of thirst. The quantities she received were as follows:

Intravenous infusion 1 pint.

	By appendix.	By mouth.
First day (in 7 hours) ...	3 pints	2 oz. (vomited)
Second day ...	4 pints	12 oz. "
Third day ...	4 pints	23 oz. (retained)
Fourth day ...	6 pints	20 oz. "
Fifth day (12 hours) ...	3 pints	24 oz. "

Total ... 20 pints ... 3 pints 7 oz. retained

No attempt was made to give a maximum quantity on each occasion.

When the appendix stump is no longer required it is treated according to the amount of sloughing present. In two cases a touch of silver nitrate was required to close it. In the rest boric fomentations or wet dressings were used for a few days. In no case was there any real trouble, the track being evidently shut off early by adhesions and granulation tissue.

The chief points about this method are as follows: There is none of the intolerable thirst so common after severe abdominal operations. The pulse slows quickly and the blood pressure rises. There is very little restlessness. The skin is moist, the mouth and tongue are clear and moist. The kidneys act well. Peristalsis is markedly stimulated. Incidentally the appendix is eliminated; with regard to the frequent presence of chronic disease in the appendix this is important. The patient is fed without disturbance, whether awake or sleeping. There is no futile coaxing of the rectum to fulfil the functions of the colon, and the stomach is allowed to rest.

THE TECHNIQUE OF ADENO-TONSILLECTOMY.

BY

JAMES C. G. MACNAB, M.D., F.R.C.S. ED.,
SURGEON, EAR, NOSE, AND THROAT DEPARTMENT, JOHANNESBURG GENERAL
HOSPITAL; LECTURER IN OTO-RHINO-LARYNGOLOGY, WITWATERSRAND
UNIVERSITY.

It appears to be generally agreed that if a tonsil has to be removed this should be done completely. It is often impossible to decide whether the tonsil is healthy or not. In markedly diseased tonsils the diagnosis is not difficult, but this applies only rarely to children, from whom 50 per cent. of tonsils are removed for reasons of size and because they give rise to more or less difficulty in breathing. I believe, however, that after the age of 5 nearly all tonsils are useless, and are in most cases a danger to the child's health at that time or later.

Enucleation with a guillotine seems to be the best method, and I have consistently used it since 1910. During a visit to Newcastle in 1908 I saw operations with the reversed guillotine for the first time, but being then in general practice I did not attempt it myself. While on a voyage to South Africa in 1910 I spent an hour daily in the study of Ballenger's description of Sluder's method, and on beginning ear, nose, and throat work in Johannesburg I employed this method, using no other in children under the age of 13. The usual guillotines had not then been reinforced, but within a few months Down Bros. and Mayer and Meltzer produced two very serviceable guillotines, though with the drawback, in my opinion, that the blades had dagger points. Then came Ballenger's handle guillotine—a very satisfactory instrument, now extensively used. This was followed by O'Malley's square blade, which impinged on a blade of soft metal when pressed home. Later came the Elphick pattern, with the crusher and blade; following this was Howarth's double blades, one blunt, one sharp, and a variety of other patterns in America, including those of La Force, Beck, and Sluder. For some time I used the La Force pattern with considerable success. With any of these guillotines I should say that 90 to 95 per cent. of tonsils can be completely enucleated. But there remain 5 per cent., which include the long, flat tonsil; the small buried tonsil glued to the pillars, especially the anterior pillar, as the result of frequent tonsillitis; and tonsils which have been previously operated upon.

Most of my tonsil operations during the last thirteen years have been performed under ethyl chloride anaesthesia. During a visit to America in 1921 I visited Sluder's consulting room in St. Louis, where I studied his original life-sized diagrams, which have now been incorporated in his book, and I often operated under his supervision. I thus learned that by following accurately the steps defined by him the 5 per cent. of impossible tonsillectomies soon dwindled to 1 per cent. The anaesthetic used was gas, and the guillotine was the Sluder pattern, of which there are three sizes. In this instrument the handle and shank are in one piece; the handle, somewhat oblong and very

strong, is placed at the correct angle to the shaft. The distal end of the shaft is as fine as possible compatible with strength; in Sluder's first step in the operation it is fine enough to separate the tonsil from the tongue should they be continuous, as well as to separate easily the lower pole. The fenestra is oval, and in the recent pattern, when the blade is driven home with the thumb, a small lever is raised which locks the blade against the concavity of the fenestra, a solid piece of soft metal taking the place of the usual slot into which the blade enters. The instrument being locked can be kept on the tonsils as long as is desirable, provided the anaesthetic is ether or a combination.

Instruments made without a small slot are more difficult to manipulate, in that the tonsil capsule is not cut through when the blade is driven home, and Sluder's seventh step is often needed, the instrument being rapidly and forcibly raised out of the mouth at a right angle to the tension of the palate. This movement transforms the action of the blade from that of a chisel to that of a knife, facilitating its cutting power. This guillotine gives an almost bloodless operation in a large percentage of cases, the adenoids being removed by a Beckman curette, which I consider the safest of all.

For patients between the ages of 13 and 17 the anaesthetic is ether with oxygen, and the locked guillotine is retained in position for three minutes after removal of the tonsil. Should there be any oozing the enucleated tonsil is fixed on a volsellum, the raw surface being distal, while the buccal surface is rapidly rubbed with 5 per cent. tincture of iodine. The tonsil is then replaced in its fossa and retained there rather firmly for two minutes. This will arrest all the general oozing, and in most cases when the tonsil is again removed the fossa is perfectly dry, any bleeding that continues coming usually from the upper pole (descending palatine artery), more towards the middle line and anteriorly. While the fossa is being kept dry with a small Soronsen's electrical exhaust pump the tonsil is picked up with a long pressure forceps and tied with a slip-knot. A full description by Coakley of this method appeared in the *Journal of Laryngology* for January, 1922. After dealing with both tonsils the adenoids are removed by Kelly's direct-vision adenotome, with which the adenoid mass is plainly seen; it removes all the tissue in about 85 per cent. of the cases. As is known, the contour of the post-nasal space varies, and occasionally a small mass may require removal with an ordinary curette, particularly if it is situated at the upper and outer angle of the space.

In patients over 18 years of age I prefer removal of the tonsils by dissection under local anaesthesia, the posterior accessory palatine nerve being blocked as it emerges from the tip of the pterygoid plate, followed by infiltration with novocain and adrenaline. Unfortunately, about ten minutes must elapse before the operation is commenced. The tonsil capsule is then seized above and below with a powerful volsellum and drawn out; it is divided with a Mayo curved scissors, also used as a plain and expanding dissector. After separation of the upper pole a long strip of gauze is inserted and carried behind and externally until the tonsil is hanging by its lower pole. A strong French snare (Lermoyez) of No. 7 piano wire is then slipped round it and the thumb-screw tightened, but not so as to cut through. It may then be left hanging from the angle of the mouth while the other tonsil is dealt with. Should bleeding occur the tonsil is slipped back into its place and held there for a couple of minutes. If either of the three vessels requires ligaturing it is picked up and tied in the usual way. The cocaine gauze packing which was previously inserted into the post-nasal space is now removed, and any adenoids excised by the direct-vision adenotome. The blood lost by this method is seldom more than half an ounce. The patient is kept under the influence of morphine for the first twenty-four hours, and pain is relieved by gargles of aspirin or antipyrin; frequent hot Vichy water gargles are given, followed by salol.

In every tonsil operation, whether in a child or an adult, the patient should be re-examined during the subsequent six to twelve weeks and a note made of the throat condition. In a town like Johannesburg it is comparatively easy to follow up such cases, and it is surprising

to see the results of some tonsil operations. Usually the condition of the throat is all that could be desired, but in an appreciable number of cases the lower pole of the tonsil—or, at any rate, tissue like that of the tonsil—remains present. It is difficult to say whether some part has been overlooked at the operation, or whether an inroad from the lingual tonsil has occurred, Nature endeavouring to compensate by depositing adenoid tissue. It is sometimes comparatively easy to see that tonsil tissue has been left; this is of little importance, as it can be readily removed. What is far more serious is an entire absence of the anterior pillar, which materially interferes with the singing voice, both in the child and adult.

When the crushing guillotine was first placed on the market many thought it would obviate most of the bleeding, but it was quickly discovered that both primary and secondary haemorrhage was far more frequent than with the single-bladed guillotine, and that about 10 per cent. of children had no vestige of the anterior pillar left, though the difficult tonsils mentioned above had scarcely been touched. The loss of the anterior pillar cannot, however, be wholly attributed to the crushing instrument, as it is occasionally found with a single-bladed one, no matter how carefully the operation is performed. Recently I saw a small boy whose tonsils had been removed by dissection. The anterior pillars had completely disappeared; so there must be other causes for this than the actual operation. I believe it will be found that these children are of a special type from the endocrine point of view, and, from my own limited observation, I look upon them as belonging to the status thymico-lymphaticus group, allied to the vagotonic (constitutional inferiority) class of Eppinger and Hess. These children are more vulnerable to infections, and on their tissues slight traumatism has far-reaching effects.

My experience, derived from many visits to schools in England, Scotland, and America, was that in children the guillotine was the method of choice, while in adults favour was equally divided between the guillotine and the dissection methods, with a slight bias towards the latter. In the Mayo Clinic dissection under local anaesthesia in the sitting-up position in a tonsil chair is favoured; in the Sluder Clinic at St. Louis the guillotine; in the North Chicago Hospital Beck's guillotine snare; in the Philadelphia Skillern Clinic the La Force crushing guillotine is used, but since the guillotine is retained from five to seven minutes before being released this may be called a bloodless method.

MEDICAL, SURGICAL, OBSTETRICAL.

INGUINAL HERNIA CONTAINING A RUDIMENTARY HORN OF A BICORNUATE UTERUS.

THE following case is considered worthy of record owing to its comparative rarity, for Latteri¹ in 1923, in describing a case, was able to find only seventy-seven other cases in the literature. He concludes that the uterus can only enter a hernial sac when some congenital abnormality is present, either of the uterus, or in the development of the canal of Nuck and the genito-inguinal ligament. He considers that diagnostic points are: pain and increase in volume of the hernia at the menstrual periods; lengthening and narrowing of the vagina, with marked inclination to the side of the hernia, which is usually on the left and irreducible, while on bimanual examination the movements imparted to the vaginal walls and cervix are transmitted to the contents of the sac. Latteri considers that operation should be undertaken as soon as the condition is diagnosed, to obviate the possibility of complications, and in particular the complications which may ensue if pregnancy should supervene; the procedure adopted should aim at reduction of the contents rather than hysterectomy.

A married woman, aged 32, was admitted to the Royal Infirmary, Sheffield, on October 17th, 1925, for operation on an irreducible left inguinal hernia. The rupture was first noticed after a fall at the age of 9 years, but gave rise to no trouble

¹ Latteri, F. S.: L'Ernia Inguinale dell'Utero, *Arch. Ital. di Chir.*, 1923, 7, 39.

until puberty, after which it became painful and increased in size at the periods, and during her one pregnancy. For five months she had had attacks of pain localized in the swelling, and occasional vomiting, particularly at the menstrual periods. The bowels were constipated, and there was nocturnal frequency of micturition. For the same period menstruation had occurred twice monthly, for two or three days, and had been painful. She had one child, aged 4½, and had had no miscarriages. Morning sickness was troublesome and persistent, and the hernia was painful and swollen during the whole pregnancy. Delivery was instrumental, but, apart from the hernia, nothing abnormal was then noticed by her medical attendant (Dr. Michael Pettigrew).

Examination revealed an irreducible inguinal hernia in the left groin, which was tender on palpation; and from the history and examination it was thought that the left ovary might be contained in the sac.

At operation the sac was dissected out after separating off well developed muscular and internal fascial coverings. On opening the sac the fimbriated end of the Fallopian tube was recognized, and the tube and its mesentery were found to be continuous with an elongated rounded muscular structure which also occupied the sac and ran back into the abdomen through the internal abdominal ring; near the external ring, where it joined with the Fallopian tube, it became adherent with the apex of the sac, and its muscular fibres appeared to run into the round ligament which continued through the external ring outside the sac. On gentle traction on the tube and its mesentery the ovary slipped out through the internal ring. On bimanual examination it was apparent that the cervix was continuous with a larger right cornu and with this smaller left cornu, which could be traced into and dragged on as it lay exposed in the open sac.

The apex of the uterine horn was freed and replaced with the tube and ovary inside the abdominal cavity, and the sac and canal were dealt with in the usual way.

Honorary Assistant Surgeon, Royal Infirmary, Sheffield.

A VAGINAL CALCULUS.

An instance of this extremely rare condition, recorded by Lieut.-Colonel W. F. Brayne, was published in the *JOURNAL* of January 2nd (p. 17). It is of interest that a small vesico-vaginal fistula was present both in Colonel Brayne's case and in that recorded below.

The patient, married six months previously, complained of dyspareunia. On examination a large cone-shaped calculus was found filling the vagina. It weighed 5½ oz., and was densely hard. Urine flowed from the vagina during the examination. An anaesthetic was given and a perineal section performed before the calculus could be removed. A portion broke off revealing a nucleus as large as an acorn, and section showed that it was an oxalate calculus, the surrounding deposit being of hard phosphatic material impregnated with blood. A fistula, admitting the tip of a finger, was found at the junction of the urethra and bladder. Careful inquiry elicited no history of bladder trouble other than incontinence, from which the patient had suffered since childhood.

Assistant Gynaecologist, Royal Victoria Infirmary,
Newcastle-upon-Tyne.

ACTINOMYCOSIS OF THE APPENDIX.

The following case is of some interest in view of the comparative infrequency of the condition, and also in demonstrating the response of the disease to appropriate medicinal treatment.

A cowman, aged 50, when admitted to hospital stated that two days previously he had been seized with diffuse and generalized abdominal pain. Later he began to vomit frequently. Next day the pain became localized to the right iliac fossa. His bowels had been open regularly without difficulty and there was no abnormality of micturition. He looked very ill, the temperature was subnormal and the pulse 80. Nothing abnormal was discovered in the chest. The abdomen was distended and moved very little with respiration. It was generally rigid and very tender in the right iliac fossa.

At the operation, which was performed by Dr. T. Turner, the lower part of the peritoneal cavity was found to contain some brownish pus. The appendix, which was removed, was very inflamed and contained a whitish concretion. A large drainage tube was put down to the pelvis.

The pathological report, by Dr. A. G. Shera, stated that films from the pus showed many streptothrix threads, but on culture only a few colonies of *Bacillus coli* were obtained. The concretion was faecal in nature and was infiltrated with streptothrix actinomycetes.

The wound was very slow in healing, and it was observed that there was a rapid tendency to the closing of the sinus following on the administration of potassium iodide in large doses combined with irrigation with tincture of iodine, 1 drachm to the pint.

Within five weeks the patient was quite well.

No history of any lesions in the common regions of the tongue, jaws, or lungs could be obtained, nor were any

signs in these places apparent. The patient's occupation is interesting in considering the etiology of the disease, as is also the remarkable response to specific treatment.

C. F. J. BARON, M.R.C.S., L.R.C.P.,
House-surgeon, Princess Alice Hospital, Eastbourne.

MIDDLE MENINGEAL HAEMORRHAGE IN A BOY.

In view of the comparative rarity of such cases, and the importance attached to diagnosis, the following case is thought worthy of record.

A boy, aged 12, was sliding between 10 and 11 a.m. on December 6th, 1925, when he tripped and hit his head on the ice; he lost consciousness at once, and was taken home. He recovered consciousness in two hours, and was able to sit up and answer questions; he complained of intense vertical headache, and felt sick, but did not actually vomit. At 3 p.m. he was growing irritable, and at 4 p.m. he became very drowsy, and paid no attention to his surroundings. He was seen by his doctor and sent to Preston Royal Infirmary for observation.

On admission at 6.30 p.m. he was unconscious. Respirations were 20 a minute and stertorous; the temperature was 98° F., the pulse full and bounding, 90 a minute. There was no facial paralysis. Marked spasmodic twitching of the right arm and leg was present; the right knee-jerk was exaggerated, and the plantar response flexor. The left arm was rigid and motionless; the left leg was motionless, but could be flexed at the hip and knee. The left knee-jerk was markedly exaggerated, and the plantar response extensor. The right pupil was dilated, irregular in outline, and did not respond to light. The left pupil was circular, not dilated, and reacted to light.

A diagnosis of right middle meningeal haemorrhage was made, and a subtemporal decompression over the bifurcation of the right middle meningeal artery was performed by Mr. McKerrow at 8.30 p.m. No anaesthetic was used, as the boy was still unconscious. A large extradural pulsating clot was exposed; the artery was not seen owing to continuous oozing from the wound. As much clot as possible was removed, and the wound irrigated with hot saline, and packed lightly with gauze soaked in adrenaline. There were signs of returning consciousness at the end of the operation.

Anti-shock treatment was given on return to the ward, and haemostatic serum administered every four hours, but the boy died at 6 o'clock the following morning, without having regained consciousness.

Permission for a post-mortem examination was refused.

I am indebted to Mr. McKerrow for permission to publish this case.

W. A. SIMPSON, M.B.,
House-surgeon, Royal Infirmary, Preston.

ACUTE APPENDICITIS IN THE AGED.

In the *BRITISH MEDICAL JOURNAL* of September 26th, 1925 (p. 584), Dr. Brian B. Metcalfe reported a case of appendicitis in a man aged 80, and asked for information as to the greatest age at which operation had been done. The following case may be of interest.

In March, 1921, a rather stout lady, aged 88, a sufferer for many years from diabetes, became ill with the usual symptoms of appendicitis. She had had a slighter attack about a year previously. On the third day, after consultation, Dr. George Clemens operated by the usual oblique incision and removed an acutely inflamed appendix which was adherent to the surrounding bowel by masses of lymph. The wound was closed without drainage. As the patient was subject to bronchitis, eucaïne was injected along the line of incision and I gave chloroform throughout.

The general condition was critical for about a week after operation, and in the second week an area of about 1½ square inches of skin and underlying fascia sloughed. Subsequently recovery was complete and she lived three years, surviving an intracapsular fracture of the femur about eighteen months.

Westbury, Tasmania. B. ANDERSON, M.B., C.M.Aberd.

OSSIFICATION OF THE CONOID LIGAMENT.

SOME time ago I attended a man who fell off his bicycle and struck the ground with the point of his shoulder (the tip of the acromion process). He had considerable pain on making any attempt to move his arm; the pain was situated over the outer third of the clavicle. The skin was discoloured over the seat of injury, and crepitus was very distinct when the outer part of the clavicle was moved. A skiagram showed no fracture of any part of the clavicle or acromion process, but there was a fracture of the conoid ligament, which was ossified, and the crepitus on moving the bone was transmitted through the clavicle.

Reports of Societies.

VITAMINS.

At a meeting of the Section of Comparative Medicine of the Royal Society of Medicine held on January 27th Professor R. H. A. PLIMMER read a paper upon the relation of quantity of vitamin B to quantity of food.

Professor Plimmer gave an account of a series of experiments conducted during the past two years, designed to determine quantitatively how much vitamin B was needed to maintain health, and how this quantity was affected by alterations in the total quantity of fats, carbohydrates, and proteins in the diet. The chief series of experiments were performed on chickens fed on a diet of rice and fish meal with cod-liver oil and yeast extract as the sources of vitamins A and B respectively. It was found that 8.6 per cent. of yeast extract was needed to maintain health on a basal diet containing 5 parts of fish meal, but that when the protein in the diet was increased by raising the fish meal to 30 parts deficiency symptoms appeared, the most striking of which were deficient bone formation and bow legs. These and other similar experiments proved that when the protein of the diet was increased the vitamin B supply also needed to be increased to maintain health. Similar experiments were performed with the addition to the diet of fats in the form of cotton-seed oil. The addition of 20 parts of this to the diet caused ill health. The chief symptoms of ill health in this case were dirty plumage and a deficient growth of feathers. An increase in the yeast ration prevented the appearance of these symptoms. Finally, feeding chickens with excess of carbohydrate also caused ill health in birds receiving a yeast ration which proved sufficient for animals fed on the normal basal ration. The symptoms of ill health in this case was defective growth and considerable fatty infiltration of the intestines. Such symptoms developed in birds receiving 8 parts of yeast, whereas birds receiving 16 parts of yeast developed in a perfectly normal manner.

Other experiments were performed on pigeons, and in these the quantitative results were even clearer, for birds receiving a ration containing 8 per cent. or more of yeast extract developed normally, whereas birds receiving less than this amount died of polyneuritis in about twenty weeks. (Pigeons fed on a diet completely devoid of vitamin B developed polyneuritis in about three weeks.) In the case of rats the graded effects produced by varying quantities of yeast extract were equally striking. Animals deprived of vitamin B—that is, receiving no yeast extract—died in about nineteen weeks. One per cent. of yeast extract in the diet prolonged life indefinitely, and a few females became pregnant, but ate all their young at birth. Animals receiving 2 per cent. of yeast extract produced more young, but likewise ate all their offspring, whereas animals receiving 4 per cent. yeast extract reproduced regularly and nourished their young.

These experiments showed in the first place that there was a marked specific difference in the vitamin B requirements of animals. The amount of yeast extract needed in the diet by different animals was approximately as follows: fowls, 12 per cent.; pigeons, 8 per cent.; rats, 4 per cent.; cats, more than 4 per cent. These figures, Professor Plimmer concluded, suggested that man probably required a vitamin B supply equivalent to about 8 per cent. of yeast extract in the diet. Secondly, the experiments showed that the vitamin requirement of an individual could be expressed by the formula

$$\frac{\text{Vitamin B supply}}{\text{Total food}} = \text{constant.}$$

This conclusion was a modification of a suggestion of certain French workers who had suggested that

$$\frac{\text{Vitamin B supply}}{\text{Carbohydrate in food}} = \text{constant.}$$

The experiments showed very clearly that one of the chief effects of a partial deficiency of vitamin B was to produce intestinal stasis which resulted in the retention in the bowel of putrid food residues and the absorption of products of putrefaction. McCarrison had noted this

intestinal effect as a preliminary stage in the production of polyneuritis in pigeons deprived completely of vitamin B. In the experiments described in which there was only a partial lack of vitamin B, this stage, which was only a temporary one in the acute experiments, became a chronic condition.

Professor Plimmer suggested that the fundamental effect of vitamin B lack was to produce atony of the gut, and that polyneuritis was possibly due to absorption of some toxic products of putrefaction. He pointed out that these experiments raised the very serious question as to whether the supply of vitamin B in normal human diets was really adequate.

To throw light on this point he had made quantitative tests of the vitamin B content of certain common foodstuffs. Pigeons were used for this test, and the criterion taken was whether the animals on the diet remained healthy over long periods and produced fertile eggs. The animals were fed on the foodstuff and varying percentages of white rice were added, and the degree of dilution determined below which symptoms of vitamin B deficiency appeared. It was found that the following percentages of varying foodstuffs were needed in the diet to provide an adequate amount of vitamin B:

Whole meal ...	75%	Bran (middlings) ...	30%
Rye ...	55%	Wheat germ ...	10%
Whole barley ...	65%	Yeast extract ...	10%
Oatmeal ...	95%	Potatoes ...	90%

Dried fruits and dried cabbage given in as large quantities as the birds would eat were inadequate. Professor Plimmer showed that in an ordinary human diet, out of a total of about 3 lb. of food there were only about 6 oz. of foods containing significant quantities of vitamin B. He suggested that the ordinary daily diet was seriously deficient in vitamin B, but that the tendency to intestinal atonia thus produced was counteracted to some extent by the widespread use of purgatives.

Professor J. C. DRUMMOND contributed a paper on the new facts concerning fat-soluble vitamins. He gave a short history of the identification of these vitamins, and mentioned that the growth-promoting fat-soluble vitamin A was identified by McCollum in 1913. In 1919 Mellanby showed that the lack of a fat-soluble factor was concerned with the production of rickets, and in 1922 McCollum brought forward definite proof that this antirachitic factor, now called vitamin D, was a separate entity from vitamin A. Evans during the past few years had shown that there was a third fat-soluble factor (vitamin E) which was necessary for reproduction. Professor Drummond explained that he wished to show that the vitamins were not mere hypothetical substances, nor even bodies of completely unknown chemical structure, such as the bacterial toxins, but that they were substances concerning whose chemical nature a good deal was already known. He described the fractionation of cod-liver oil, and showed that the whole of the fat-soluble vitamins were contained in the 1 per cent. of non-saponifiable matter in the oil. Half of this active residue was cholesterol and was inactive. Fractional distillation of the remainder under low pressures showed that the whole of the active portion was contained in the fraction boiling between 180° and 200° C., at 1 to 2 mm. Hg pressure. This active fraction consisted very largely of an unsaturated alcohol, and contained only the elements carbon, hydrogen, and oxygen. The daily dose of the most active fraction was only 0.002 mg. for a 100-gram rat. The recent work on the production of the antirachitic vitamin by ultra-violet light gave much information as to the chemical nature of the antirachitic vitamin D. The discovery of Steenbock that irradiation of food caused the production of vitamin D had led to a large amount of work, which first showed that only oils and fats could thus be activated, and next showed that only the unsaponifiable matter in fats could be activated. Finally it was shown that the exposure of chemically pure cholesterol to ultra-violet light caused the formation of vitamin D. Prolonged exposure of waxy material that had an intense antirachitic action. Professor Drummond pointed out that this last discovery meant that one of the vitamins had actually been synthesized, and that there was

every reason to hope that before long the exact chemical nature of some of these substances would be known.

The papers were followed by a discussion in which a number of Fellows took part.

Dr. ROWLANDS pointed out the high importance of the two papers. Professor Plimmer's proof of the association of intestinal stasis with lack of vitamin B was of great clinical importance. In this country beri-beri was almost unknown, but intestinal toxæmia was extremely common. He expressed the belief that rheumatoid arthritis was chiefly intestinal in origin. Dr. HALLÉ DALLY raised the question of the relation between intestinal toxæmias and high arterial tension.

Dr. ANDREWS said that he had watched experiments at Pretoria on feeding horses and cattle on vitamin B deficient diets, and that this had caused no definite effects of avitaminosis, but that numerous minor effects, such as digestive disturbances and laminitis, had occurred. Other speakers emphasized the great importance of the public health aspects of the problem of partial vitamin deficiency, and the importance of informing the public about the ascertained facts.

In reply, Professor PLIMMER said that the essential point he wished to make was that the population of this country was living on a diet partially deficient in vitamin B. His experiments suggested that the amount of wholemeal bread needed for an adequate supply of this vitamin was about 75 per cent. of the total diet. He pointed out the disadvantages of such foods as milk puddings made from vitamin-free white rice with a little milk.

Professor DRUMMOND mentioned that only vitamin D could be synthesized by ultra-violet light from cholesterol or fats, and that the other two fat-soluble vitamins had not been synthesized in this manner.

CLINICAL ASPECTS OF SIMPLE GOITRE.

At a meeting of the Hunterian Society held in the Hastings Hall at the British Medical Association House, Tavistock Square, on January 25th, with Dr. HOWARD HUMPHRIS (President) in the chair, Sir JAMES BERRY delivered a Hunterian Lecture on "Some clinical aspects of simple goitre, with remarks on its causation."

Sir James Berry opened with a reference to John Hunter, who, he said, would have entered with characteristic zeal and enthusiasm upon the fascinating study of the thyroid had he not lived in a time when very little was known about that gland, which consequently was of little interest to the surgeon. Goitres, other than malignant and some rare forms, might be classified as (1) ophthalmic goitres, with excess of the cellular elements of the gland, essentially a hypertrophy, and (2) simple goitres, which were essentially degenerations of the gland, showing distension with colloid and atrophy of the epithelial elements. In later stages there were cysts, masses of ill formed thyroid tissue more or less encapsuled (adenoma), fibrosis, and calcification. These were produced by the long-continued action of some irritant. The pathological and clinical pictures of exophthalmic and simple goitre were strikingly different in typical cases. He discussed various difficulties in diagnosis which might arise. One difficulty occurred where symptoms of Graves's disease supervened on simple goitre. Again, in simple goitre tachycardia and tremor might occur, especially in the deep-seated substernal condition, and such cases were often classified as Graves's disease or hypertrophy; this the lecturer considered to be undoubtedly incorrect, and to lead to confusion in statistics. Acute catarrhal conditions or sudden hæmorrhage into a soft encapsuled goitre might produce tachycardia and irregularity of pulse; and, further, septic foci in distant parts of the body, such as the appendix, in cases where a goitre was present might also cause these symptoms, which had nothing to do with the goitre. Colonel McCarrison, by giving animals food polluted by faecal matter, obtained an enlarged thyroid, but of the hyperplastic form.¹ Colloid distension was only obtained when excess of lime was added. The view that simple goitre

was a degeneration, not a hypertrophy, was in direct opposition to what was adopted generally by those who experimented on animals without much previous experience of the disease as it occurred in man.

The lecturer said that he did not propose to discuss the various theories of the causation of endemic goitre, because these could be found in the textbooks; but he wished to mention one theory which had attracted much attention lately—namely, that lack of iodine in food or water was the main, if not the only, cause of goitre. This was really the revival of an old theory of three-quarters of a century ago. Iodine was useful in the treatment of goitre, especially of the early forms, but there was no real evidence to show that it had a causal relation to endemic goitre. It had been stated that goitre was absent near the sea coast, and this was attributed to the iodine in sea air. But there were many places near the sea coast which he had himself visited where goitre did exist. The principal districts where endemic goitre was known comprised the great mountain ranges of Europe, Asia, and America, such as the Alps, Pyrenees, Himalayas, and Andes, also the Alps of New Zealand. All these were, in the geological sense, young mountains. Goitre was not prevalent in the worn-down older formations, the remains of former higher ranges, like the Highlands of Scotland, crystalline rocks such as those of Western Norway, and volcanoes, extinct and active. In the ranges just mentioned where endemic goitre was prevalent, an interesting point was the existence of glaciers, especially in the most goitrous regions, the glaciers producing turbidity of the rivers by their constant grinding action. The green or blue of the Swiss lakes was due to finely suspended mineral particles, and was in striking contrast to the clear waters of the Scottish lakes. Not only the existing glaciers but the glacial debris which covered so much of Switzerland produced streams of similar character. In any hilly country sedimentary pollution of the streams might occur where the rocks were soft and easily eroded. The lecturer had himself noticed that goitre was common among those who drank turbid water, and he knew of many instances where the introduction of a better water supply had largely diminished the incidence of goitre. The attempt to prevent endemic goitre by introducing iodine into the water supply was, he considered, of doubtful value, and unnecessary in a country like Great Britain, with no very high endemicity.

In conclusion, the lecturer said that he wished to emphasize the point that simple endemic goitre was not a hypertrophy, but essentially a degeneration of the thyroid gland; the gland was not overactive but underactive. Whatever might be the connexion between iodine and the thyroid gland, there was no reason to believe that a lack of iodine had anything to do with the causation of endemic goitre as found in the human subject. In the vast majority of cases it was quite certain that the disease was produced through the agency of drinking water. There was much evidence that practically all waters which produced goitre contained frequently—although not necessarily at all times—mineral matter in suspension, usually in an extremely fine state of subdivision. There was also a good deal of evidence that this mineral matter was generally of a calcareous nature. Organic matter in suspension, although capable of causing, apparently, a hyperplasia of the gland, at least in animals, had not been proved to be the cause of endemic goitre as seen in man. Sir James Berry's lecture was illustrated by the epidiascope.

Dr. STRICKLAND GOODALL referred to a patient, whom he first saw as long ago as 1903, suffering from laryngitis, rapidly losing weight, and having a very irregular heart. Even at that time he thought that the cardiac condition had something to do with goitre. The irregularity of the heart was similar to the irregularity in mitral stenosis towards the latter end. He described the records which he took then and later, including electro-cardiograms, and said that about 1912, when the condition of auricular fibrillation was described, he had recognized this irregularity, originally noticed in 1903, as being identical with it. After further experience of patients suffering from goitre, he had been impressed by the number of patients who died suddenly either before or after operation, and, with Dr. Lambert Rogers, in trying to investigate the

¹ BRITISH MEDICAL JOURNAL, June 7th, 1924, p. 983.

cause he had collected some interesting specimens to show the degeneration which took place in the heart muscle.

Mr. T. P. DUNHILL said that the chaos which had characterized the subject of goitre up to the present decade was being cleared away, and the subject was now becoming intelligible. Although very many problems remained to be solved, it was now possible to work along more sure lines. Many men had made different contributions which could now to some extent be sorted out and placed in their proper perspective.

Dr. SCOTT WILLIAMSON thought it probable, at first sight, that endemic goitre must be regarded as consisting of at least two forms. One of these might well be caused by something in the nature of calcareous matter suspended in drinking water. The addition of calcium to the thyroid in animals could produce this, the colloid variety of goitre. The other type, which Gaylor had described as endemic in the fish-breeding tanks, had little or no relation to the colloid goitre. It was controlled very easily by pharmacological doses of iodine added to the water, and it had been demonstrated that where this condition arose there was a considerable lack of iodine. This had led to the use of iodine for endemic goitre. The more closely endemic goitres were examined the more clear it became that there was one type of endemic goitre in which, if iodine were administered, very serious toxic disturbances were induced. In association with Mr. Dunhill he had been making experiments on the action of iodine. The thyroid gland was fundamentally lymphatic, and in applying iodine to it care was taken to control the experiments by the inspection of other organs in the body. If iodine were given to an animal which had been put into the colloid state, the gland would slightly enlarge, and then soften; the liver, pancreas, and kidney were also profoundly affected. Iodine accentuated the activity of the gland, which had a general effect on the whole body.

The PRESIDENT, referring to the geological aspect of the problem, said that for some years he had lived on a volcanic island in the middle of the Pacific, and there he had never seen a single case of exophthalmic goitre, either in hospital or in private practice.

Dr. COLE asked if the absence of sunlight was not one of the factors contributing to the presence of goitre. In New Zealand goitre occurred among the people living in the narrow valleys, but not among those who lived on the tops of the hills, and generally not among the people of the plains. There were also exceptional cases of goitre in the Swiss valleys where there was little direct sunlight, and the same was true of other parts of Europe and of Palestine. The theory appeared to be supported by the fact that actinotherapy was beneficial in goitre.

Mr. MORTIMER WOLF said that surgeons tried to conserve the thyroid, and, in any operation, to remove as little of it as was consistent with the suitable treatment of the patient. With regard to a remark by Sir James Berry that the majority of simple goitres were to be viewed as significant of a degenerative process rather than a hypertrophy, he thought that this might explain some of the difficult cases in which there were symptoms reminiscent of Graves's disease. He felt confident that many of the cases which he had seen classified as exophthalmic goitre were actually cases of hypothyroidism. It might be difficult to imagine that a patient with a large swelling in the neck was suffering from a lack of thyroid secretion, but he was convinced that it was true.

Dr. W. LANGDON BROWN agreed that there were many cases of enlarged thyroid due to lack, rather than excess, of secretion. There were many ways of determining between the two types, and his experience was that the basal metabolic rate gave the best indication as to whether a patient with an enlarged thyroid was suffering from oversecretion or lack of secretion. It was much better to study the matter in that way than to take the blood sugar curve, because in border-line cases the latter was not the help that it might be. Professor Mellanby, in one or two papers, had furnished some evidence that there was a condition which led to the abstraction of iodine from the gland and from the body. The speaker related some experiments in Canada in 1921 illustrating the influence of iodine in preventing goitre. These experiments were started owing

to the occurrence of goitre among lambs. Some of the observations made on animals had been of great value; animals were not so liable to suggestion as human beings, and there was better opportunity for observation without interference by the nervous system. In the experiments referred to, 89 ewes were dealt with: of these, 23 were separated as a control group, and the remainder were divided into three batches of 22. The first batch were fed on the rations they had had the previous year; the second had the same rations, with exercise in addition—that is, the food was placed some distance away, and the ewes had to go that distance to reach it; the third had the same ration, with a 2 per cent. solution of potassium iodide; and the fourth had a diet rich in vitamins. The first group had 38 per cent. of goitres, the second 45 per cent., the third (where potassium iodide was added) had none at all, and the fourth had 38 per cent. Factors of this sort seemed to him to suggest that iodine did play a very considerable part, one much more important than many people, particularly some surgeons, were prepared to admit, perhaps because they did not allow for certain factors not yet fully understood which removed iodine from the gland and from the body.

Sir JAMES BERRY, answering Dr. Cole, said that absence of sunlight could not be the cause of goitre, for many people, such as miners, who spent their working hours in the dark, did not get goitre, nor did the pit ponies which spent their whole lives underground. It was true that stout people seldom had goitres; if they did one should be very chary of operation unless there was very great need. He had remarked some months ago that it was possible to get hyper- and hypo-thyroidism at the same time; there were mixed cases. He deprecated operating on children, and said that he had never operated on anybody younger than 10, and on very few children under 14. The views expressed by Dr. Scott Williamson were not very different from his own. With regard to the basal metabolic rate, he had used this a good deal at one time, but he had given it up because he could tell generally by merely looking at a patient whether the trouble was hyper- or hypo-thyroidism; he had had the advantage of having examined many thousands of goitres. He had also seen wrong statements due to error in the way the metabolic rate was taken.

HODGKIN'S DISEASE IN MAN AND ANIMALS.

A JOINT meeting of the Sections of Medicine and Comparative Medicine of the Royal Society of Medicine was held on January 26th, the President of the Section of Medicine, Dr. HUGH THURSFIELD, being in the chair.

The discussion was opened by Sir HUMPHRY ROLLESTON, Bt., whose paper is published in full at page 230 of this issue of the JOURNAL.

He was followed by Professor G. H. WOOLDRIDGE (Royal Veterinary College), who regretted that he was able to discuss Hodgkin's disease in animals only from the clinical point of view. The disease was a rare one in the domestic animals—in fact it was only in the dog that it was occasionally met with. Its true nature was unknown, and it was quite probably not the same condition as existed in man. The condition was not neoplastic, but was probably inflammatory in nature, and should properly be called lymphadenitis. The onset was slow and insidious, and the clinical picture one of progressive emaciation. The symptoms began with a cough and a catarrhal pharyngitis accompanied by a slight rise in temperature. Patients, however, were seldom seen until the condition was well advanced. At first the prescapular lymph glands became enlarged, but ultimately all the superficial glands were involved. At this stage the dog was emaciated, easily excited and tired, and might faint. There was now no pharyngitis. The spleen became enlarged, and might be easily palpated. The lymph glands were firm to the touch and painless. There was no pleuritis, no pigmentation of the skin, and the blood picture was normal. On section the lymph glands showed only hyperplasia, and were not changed in structure. Old dogs seldom recovered, but the prognosis was more hopeful for young animals. In treatment excitement must be avoided. Donovan's solution was given, together with cod-liver oil,

extract of malt, and phosphates. Digitalis and squills were prescribed in alternate weeks. So far x rays and radium had not been tried, and it was doubtful if the animals could, on economic grounds, be so treated. He had seen one case in a bull in which there was no possibility of tuberculosis; all the superficial glands were swollen, and the animal was emaciated; it was treated on similar lines to dogs, and made a complete recovery.

The mention of diphtheroid organisms by Sir Humphry Rolleston recalled the condition in sheep called caseous lymphadenitis, which was caused by the bacillus of Preisz-Nocard, an organism of the diphtheria group. Professor Wooldridge did not suggest that this disease was related to Hodgkin's disease, but the presence in animals of a condition caused by an organism related to those which had sometimes been associated with it was of interest. The sheep affected were generally in excellent condition, and the lesions were only found on examination by the meat inspector, or indeed sometimes only after the mutton had gone to the table. The gland most frequently affected was the inguinal, the "pope's eye," and it was often in a very soft caseous condition. The disease was of interest, however, in showing a form of lymphadenitis due to an infective organism.

Dr. H. MORLEY FLETCHER dealt with the clinical aspects of the disease in man. The presence of eosinophilia and the apparent success of arsenic suggested a parasitic origin of the disease. He drew attention to the pruritus which was often associated with the condition, and which was often ascribed to the arsenic used in treatment. He had seen cases, however, in which the pruritus was present before the use of arsenic. Another important point was in connexion with the relapsing fever which so often accompanied Hodgkin's disease—the so-called Pel-Ebstein symptom. This temperature curve could exist below the normal line as well as above it; and if the subnormal temperatures were plotted it was often possible to see a Pel-Ebstein curve which never rose above the normal. It was accordingly important in Hodgkin's disease to make a careful record of minimum as well as maximum temperatures. In the abdominal type the disease was apt to be overlooked, and diagnosis was very difficult. He thought that modern methods of treatment with x rays and arsenic were having better results than the older methods, although complete recovery could not yet be claimed. He would like to know if antimony had ever been used for this condition.

Mr. L. PUGH drew attention to leptospiral jaundice in dogs, which showed certain resemblances to this condition.

Professor M. J. STEWART (Leeds) described his experiments, in which he infected two series of monkeys, the first with pieces of gland and the second with pulped glandular material. He exhibited a series of microscope slides illustrating the results he had obtained. He had made an analysis of the glands which had been sent to him for diagnosis. This analysis showed only glands which fell into one of three classes. The first were those sent to him marked "Hodgkin's?"; the second marked "Hodgkin's? tubercle?"; and the third were simply "Disease?" He found that about 25, 17, and 4½ per cent. respectively were lymphadenomas, while more than half of each series were tuberculous. This, he thought, showed that a positive diagnosis could only be given after a microscopic examination.

Dr. W. H. ANDREWS (Royal Veterinary College) was afraid that his evidence was mainly negative. He considered that true Hodgkin's disease did not exist in the lower animals. In all the cases seen the histological picture was certainly not that of Hodgkin's disease. It was quite probable that the disease which existed in dogs was caused by more than a single organism. Other similar conditions existed in animals, but as the cause became known they were described under their correct name. For example, East Coast fever, a disease in cattle in Africa due to a protozoan parasite, showed similar enlarged glands. In any case, should Hodgkin's disease exist in the lower mammals there was no reason why it should exhibit symptoms identical with or even similar to those found in man.

Dr. MERVYN GARDON indicated the lines along which he had worked at the etiology of the disease. His experiments had not been successful, but he suspected a spirochaete,

and he thought that if investigators used anaerobic media they might have some success.

Dr. H. H. SCOTT recalled that he had examined a marmoset at the Zoological Gardens which he thought showed typical lesions in the lymph glands.

The Chairman (Dr. THURSFIELD), in closing the discussion, said that he was sure that the general opinion was that Hodgkin's disease as it existed in man did not occur in the domesticated mammals. The condition which was found in them should probably be called lymphadenitis rather than lymphadenoma. This was the first occasion on which the Comparative Medicine Section had met with the Medical Section, and he was sure that these joint meetings would be of value.

DICEPHALY.

At a meeting of the North of England Obstetrical and Gynaecological Society on January 15th, with the President, Mr. W. GOUGH (Leeds), in the chair, Miss K. EDGECOMBE (Liverpool), on behalf of Miss Ivens and herself, described a case of dicephalus dibrachius dipus, an unusual type of monstrosity, which recently occurred in the Liverpool Maternity Hospital.

A primigravida, aged 24, married for three years, had felt well during pregnancy, and had not had an ante-natal examination. Labour started under the care of a midwife, and two days later the breech was delivered to the level of the umbilicus. The arms were pulled down under anaesthesia, but it was not possible to deliver the after-coming head, and the patient came into hospital after she had been in labour fifty-three hours. A large sausage-shaped tumour with two rounded prominences was visible above the brim of the pelvis, the higher prominence being situated in the left iliac fossa. The uterus was contracting strongly, pains occurring every minute with incomplete relaxation between the contractions; the abdomen was acutely tender, and there was some haemorrhage from the lacerated and oedematous soft parts. The legs, body, and arms of a small dead child protruded from the vulva, the back being in front. The patient was anaesthetized, and the haemorrhage was traced to a vaginal tear extending high into the left fornix. A thickened band could be felt on the left side, resembling an incompletely dilated rigid cervix; this was not present on the right side, and was probably the stretched neck of the left head, the right head being extended immediately above the brim. The child's body was rotated, so that its abdomen faced the mother's left thigh. Delivery was effected by a combination of the Prague method with jaw traction and suprapubic pressure, the child's body being carried up over the mother's abdomen. The second or left head followed immediately, and it appeared probable that the rotation of the body had released the twist of one neck round that of the other, and so made delivery possible. Subsequently a fracture of the first neck was found. The single placenta was expelled spontaneously. After delivery the perineum and vulva were found to be badly lacerated, portions of the levatores ani hanging loose on either side of the wound.

After a mercurial douche the bruised tissues were cut away and the lacerations were repaired with silk-worm gut. Good union resulted, and apart from slight pyrexia due to a urinary infection the puerperium was uneventful. Two months after delivery the perineum had completely healed, and micturition and defaecation were normal. The Wassermann reaction was negative or indefinite on two occasions.

The specimen was a double-headed monster or dicephalus dibrachius dipus, a female weighing 6 lb. 15 oz. There were two distinct heads, two arms, two legs, and a single body, which showed, however, on x-ray examination, two distinct spinal columns, approximating in the sacral region. The shoulders were broad, and there was a tag of skin in the suprasternal region. The two heads were flattened on the inner surfaces where they had been in contact. The dissection, by Mrs. Barton Hall, showed the presence of single abdominal and thoracic cavities, with one sternum and two clavicles. There was a single heart and pericardium, with one auricle and two ventricles, two aortas, two pulmonary arteries, two superior venae cavae, and one inferior vena cava. The right aorta supplied the right head and upper limb only; the left aorta supplied the left head and upper limb, and continued as a normal thoracic and abdominal aorta. There was a trachea from each head leading to four lungs in four pleural cavities. The organs developed from the branchial arches and clefts were duplicated (tongue, thymus, thyroid). The alimentary canal was duplicated as far down as the duodenum; the left stomach opened into the first part of the duodenum; the right stomach into the second part of the duodenum. The spleen was single and in a normal position on the left side. The liver was normal in position. An accessory lobulated portion continuous with the normal liver appeared to have passed as a hernia through the diaphragm, and lay in the thoracic cavity posterior to the heart and pericardium. There was a single gall bladder and bile duct, the pancreas being double. Below the duodenum the alimentary canal was single. The kidneys, ureters, suprarenals, and female pelvic organs were those of a single foetus. On deep dissection a complete fracture of the right neck was found; the spinal cord of that side had been dragged upwards, and lay in a loop at the site of fracture.

Miss Edgcombe pointed out that since all double malformations developed from a single ovum, there was in this case a single placenta and single chorion. Under certain conditions dicephali were capable of living; the best known example was Ritta Christina, born in Sardinia on March 13th, 1829. These twins of female sex had four upper and two lower limbs (dicephalus tetrabrachius dipus). The vertebral columns, separate above, were joined below by a rudimentary os innominatum, and there was also union of the two manubria. In this malformation union of the internal organs often occurred. In the present case a pelvic presentation was favourable, as one head could pass after the other. It had been recommended to draw the trunk when expelled up over the abdomen of the mother, so as to bring the posterior head into the hollow of the sacrum; the second head then slipped up anteriorly above the pelvic brim and remained behind. Blacker (1912) had noted that of twelve cases of dicephalus recorded in the *Transactions of the Obstetrical Society* (seven in Playfair's paper (1867) and five after that date), in four the breech presented; when care was taken to cause the two heads to enter the pelvis one after the other they passed through without difficulty.

The PRESIDENT thought that the comparative ease of delivery, which appeared impossible in the specimen as shown, was largely due to the broken neck of the second head, allowing greater stretching.

Professor BRIGGS (Liverpool) emphasized the lesson to be drawn from this and similar rare specimens in favour of version, which was so often rejected both in practice and in publications. It confirmed the teaching of Potter's latest work, *Version in Obstetrics*. Rupture of the uterus was extremely rare in these cases.

Mrs. BARTON HALL (Liverpool) had studied the literature on dicephaly as far back as 1866, when Playfair collected seven cases; she found thirty-seven published cases from all parts of the world. Three main types were definable, depending upon three stages in the superior dichotomy of the primitive streak. The first group, which was rare, was the true dicephalus dibrachius dipus, of which Miss Ivens's specimen was an example. The second and common group included specimens which resembled the first group externally, but on dissection or x-ray examination they were found to have a rudimentary third upper limb in the form of a fused scapula and clavicle. The third group was the true dicephalus tribrachius tripus, and occurred with about the same frequency as the first group. She thought that the lungs and oesophagus in these cases of dicephaly were always duplicated, and the extent of the reduplication in the rest of the thorax and abdomen depended entirely upon the level of separation. With regard to the viability of these monsters, she thought that the greater the degree of separation the more chance there was of the foetus being viable, and quoted a case of dicephalus tribrachius tripus delivered alive which lived twenty-four days, but died with convulsions.

Nægele Pelvis.

Miss EDGECOMBE also reported, on behalf of Miss Ivens and Miss Brookfield, a case of Nægele pelvis, which was admitted to the rest home of the Liverpool Maternity Hospital under Miss Ivens.

There had been two previous pregnancies, the first terminating in a difficult forceps delivery with a stillbirth, the second by an induction at the thirty-eighth week, the child being 5 lb. 15 oz., and surviving. The patient was aged 23, of medium stature, and in good general health. There was no lameness, but an inspection of the pelvis showed a slight obliquity from the right, downwards towards the left. The right anterior superior spine and the left posterior superior spine were more prominent than their fellows. The labial cleft also deviated slightly downwards, and to the left. On vaginal examination the right ilio-pectineal line was found to be straight, reducing considerably the capacity of this side of the pelvis. The right ischial spine also formed a very marked projection into the pelvic cavity. The symphysis pubis was markedly deviated to the left side. The left side of the pelvis felt approximately normal. The measurements of the pelvis were as follows: Inferior strait 8½ in., internal conjugate 10 in., external conjugate 8½ in. The distance from the right posterior superior spine to the left anterior superior spine was 8.2 in., and that from the left posterior superior spine to the right anterior superior spine was 7.5 in., showing a difference, therefore, of about three-quarters of an inch.

The diagonal conjugate was 3.9 in., and the transverse diameter of the outlet 3 in. (approximate). On her admission, at about

the thirty-eighth week, the patient had a purulent vaginal discharge, coming mainly from the cervix, and also two vaginal cysts. Vigorous local treatment was adopted, but induction of labour was felt to be contraindicated on this occasion, and pregnancy was allowed to proceed to term, when Caesarean section was performed by Miss Ivens, a female child, weighing 8 lb. 4 oz., being delivered from the left occipito-anterior position. A prophylactic dose of 10 c.cm. antistreptococcal serum was given to the mother, and she made an uninterrupted recovery, being discharged on the fourteenth day after the operation. Inquiries were made from the patient's mother as to any history of deformity or dystocia in the family. All the immediate relatives had had normal deliveries and healthy families. There was no history of the patient having been lame or suffering from any serious illness during infancy or adolescence. The only conclusion seemed to be that the deformity was due to a defect in development of the right ala of the sacrum.

The obliquely contracted pelvis of Nægele was observed first in 1802. In 1839 he published a monograph on thirty-five specimens, one a mummy. It was a developmental defect due to absence of one lateral mass of the sacrum; bony union of the sacrum with the ilium was usually present, the bones being otherwise healthy. There was compensatory scoliosis of the lumbar portion of the vertebral column with its convexity on the diseased side. The obliquity was caused by the unequal pressure of the body weight and upward thrust of the femora on each side. On the defective side the femur was nearer the middle line than on the sound side, so that the pressure was upwards rather than outwards. On the sound side the acetabulum was further outwards than usual, the wing of the ilium looked more forward and less inwards than usual, and the symphysis pubis was pushed over to the sound side. On the defective side, in consequence of the more directly upward pressure, the ilium between the acetabulum and synchondrosis was compressed and thickened, and the ischial tuberosity and spine were displaced inwards, upwards, and backwards.

All specimens described were exactly alike, and there was no sign of bone disease. The defective development of the sacrum was the essential condition, although it had been suggested that the synostosis resulted from destructive inflammatory changes, but cases had been described where synostosis was not present.

Commenting on this case Miss Edgcombe said that in 1861 Thomas reported fifty cases, but the entire number was only about one hundred. For labour to end naturally the head must be small, and must enter the pelvis with the occiput towards the obturator foramen on the sound side. In labours reported only a quarter of the children had survived. Litzmann stated that in pre-antiseptic days twenty-two out of twenty-eight mothers died in the first labour. Pinard in one case performed ischio-pubiotomy on the diseased side, but was criticized by Budin on the ground that ankylosis at one sacro-iliac joint might prevent expansion of the pelvis.

Advantages of Vaginal Hysterectomy.

Professor BRIGGS read a note on the advantages of a vaginal hysterectomy, and showed two specimens, the first being a uterus with multiple fibroids, and the second one with glandular erosion of the cervix, a sessile adenoma, and an interstitial fibroid. Both had been removed by vaginal hysterectomy.

He asked, were there any advantages in vaginal hysterectomy in the treatment of these uterine non-malignant new growths? He was content with the success and safety of vaginal hysterectomy in cases where the site and size of uterine innocent new growths pointed towards treatment through the pelvic floor. Not infrequently during vaginal hysterectomy the laxity of the pelvic floor aided the operator, and could finally be corrected by him. This addition was made to the vaginal hysterectomy in the case of the removal of the second specimen; convalescence and repair were very satisfactory. In such cases vaginal hysterectomy offered bright prospects and was easy in performance. Other cases were fairly represented by the first specimen, which was capable of filling the outlet of the pelvis and of becoming fixed there pending reduction in bulk and alteration in shape.

Morcellement, enucleation, or other similar method of removing some of the group of fibroids converted an immobile ovoid or sphere into a flexible, yielding column of collapsed and partially cut walls of the uterus, surrounding any remaining fibroids. The preservation of the pelvic floor was watchfully observed. Morcellement was used in the case of tissues which were to be removed, and not retained at the patient's risk; a normal convalescence after vaginal hysterectomy was not exceptional. After Péan's introduction of morcellement in the eighties of the last century its excessive use early trespassed on the

grounds of abdominal hysterectomy; the overlapping had not been one-sided. In 1898, on the ample evidence of the day that vaginal hysterectomy for fibroids was a sound operation, Professor Briggs had published a report of thirteen cases, and confirmed the value of morcelllement at a time when the French total figures made others seem absurdly insignificant. In 1897 was published *The History and Technique of the Vaginal Radical Operation*; this was a translation by Eastman and Giles of the German work by Leopold Landau and Theodor Lander entitled *Die vaginale Radicaloperation*, which was based on Freund's publication (1878) and Péan's *Morcelllement*. In the early years of the present century (1906) was published in Leipzig a work on the technique of vaginal operations, by E. Wertheim and T. Micholitsch. This latter work the speaker had reviewed for the *Journal of Obstetrics and Gynaecology of the British Empire*, 1906, p. 188. Both those works were designed to go beyond or outside the scope of vaginal hysterectomy; they intensified the ill-advised competition of vaginal and abdominal section, hence the need for limitation followed. The article by Herbert Spencer on vaginal hysterectomy in the treatment of uterine fibroids in Allbutt, Playfair, and Eden's *System of Gynaecology* (1906) remained to-day for guidance.

The PRESIDENT said that in his earlier days he had performed vaginal hysterectomy for fibroids, some of which reached the umbilicus. Of recent years, however, he had used the abdominal route for such tumours as being easier, since the operator was able to see what he was doing. He thought, however, that vaginal hysterectomy had a very useful place in the treatment of the bleeding uterus about the menopause, as it was associated with much less shock than the abdominal operation. He had found that the convalescence was often rather delayed by discharge of pus and small sloughs from the vagina.

Dr. DONALD said that at one time he had removed uterine fibroids by vaginal hysterectomy on a good many occasions, and in some of the cases the upper level of the tumour was as high as the umbilicus. It was an interesting experience, and he thought that even at the present time a gynaecologist should be familiar with the technique. Vaginal hysterectomy should, however, be now limited to cases of chronic metritis or hypertrophy in women approaching the menopause, with fairly patulous vaginas. In these cases there was still a place for it. The convalescence was generally smooth, and free from some of the discomforts that often followed the most successful abdominal operation for fibroids.

Carcinoma of the Cervix and Pregnancy.

Dr. J. W. BURNS (Liverpool) described a case of carcinoma of the cervix in a pregnant woman aged 41.

This patient, who was admitted to hospital on March 20th, 1925, complained of pain in the back and lower abdomen, and stated that for some time the menstrual periods had been irregular, and that for the past six months there had been bleeding following coitus. More recently there had been a constant blood-stained vaginal discharge. On abdominal examination the uterus was found enlarged and the pregnant state was confirmed. The cervix was soft, and there was a ragged patch on the posterior lip which bled very freely on touching. Under anaesthesia a small portion of the cervix was removed for examination; it was found to be malignant. Total hysterectomy was performed, the operation being easy owing to the softened condition of the tissues. No enlarged glands were found. The patient made a very good recovery, and returned home within three weeks. Nine months later a small recurrence was found in the scar in the roof of the vagina. The specimen showed the uterus to be about sixteen weeks pregnant; it was opened through the posterior wall. The foetus and its membranes could be seen *in situ* with the placenta on the anterior wall. A small area of the posterior lip of the cervix shows a dark discoloration, and a section of this shows microscopically the typical appearance of carcinoma. Cancer of the cervix complicating pregnancy was a comparatively rare condition. Gross found 120 cases in 224,080 cases of childbirth, equivalent to 1 in 1,867. Sarvey collected 53 cases in

84,148 cases of childbirth investigated—1 in 1,600; Dr. Lee gave the incidence as 1 in 2,000. In the reports of the St. Mary's Hospitals, Manchester, for the years 1915 to 1923 inclusive six cases were reported in 23,867 cases of childbirth, an incidence of 1 in 4,000. The Rotunda Hospital reports for a period of twenty-five years, dealing with about 45,000 cases of childbirth, did not contain a single case. The reports of the Liverpool Maternity Hospital for the years 1916 to 1923 inclusive, and dealing with 16,680 cases of childbirth, were similarly negative. These figures, together with the fact that the speaker had been able to collect only about twenty-eight cases in British literature, would suggest that the incidence, for the British Isles at least, was much less than that given by the above authorities. It was not known whether the malignant condition usually antedated the pregnancy or developed after conception had taken place. Gross found in 16.7 per cent. of his cases that the cancer was present before the pregnancy. John T. Williams, John W. Williams, Keyes, Sarvey, and Schweitzer all agreed that in the majority of cases the cancer was present before the pregnancy. In the present case there was some evidence that the malignant condition of the cervix was present before conception could have taken place. The patient complained of bleeding following coitus for six months, and the pregnancy was only of four months' duration. Most authorities agreed that if the malignant state was discovered before the fourth month, hysterectomy ought to be performed after full explanation to the patient and her relatives. After the fourth month the pregnancy could be allowed to go to term, and Caesarean section performed with or without hysterectomy.

The PRESIDENT had seen two cases of malignant disease of the cervix complicating pregnancy. In both he had been struck by the softness of the growth and the absence of any craggy edge. In one case, which he was able to observe through labour, the cervix dilated quite easily, and delivery was normal. The case was treated by Wertheim's hysterectomy about three weeks later.

MANCHESTER MEDICAL SOCIETY.

At a meeting of the Manchester Medical Society on January 13th, with the President, Mr. A. H. BURGESS, in the chair, Dr. C. V. LAPAGE read a paper on erythroedema (pink disease).

Erythroedema.

Dr. Lapage mentioned that the disease had been first described in Australia, then in America, and more recently in Europe; the characteristic pinkness of the hands and feet had given the name to the disease. This symptom followed an onset with loss of appetite, insomnia, and other signs of failing health, combined with irritability, a malarial rash, photophobia, and stomatitis; sometimes dropping out of the teeth occurred. The differential diagnosis from toxic oedema, meningitis, tuberculosis, congenital syphilis, rheumatism with sweat rash, and other rarer conditions was not easy without previous experience, but once the characteristic persistent pinkness of the extremities, the misery, the loss of tone, and, if present, the photophobia and falling out of the teeth, had been seen the disease was easy to recognize. There was little doubt that many cases were at present unrecognized. Dr. Lapage gave a summary of twelve of his cases, which had occurred in the Manchester district during the last two years. In several of these cases the babies were breast-fed, so that the disease was probably not due to deficiency of diet. It was probably an infective condition, but so far no organism had been demonstrated. Another theory was that it was due to disease of the vegetative nervous system; this was supported by the fact that salivation, rapid pulse, high blood pressure, insomnia, mental depression, and pink oedema of the extremities occurred. The treatment consisted in alleviation of the symptoms, and in stimulation when the child was very weak and in danger of dying. Artificial sunlight did good in some cases, and attention should be paid to any discharge from the nasal passages, while removal of the tonsils had been attended

with marked improvement in some cases. Open-air treatment was also of great value if the child was kept warm. The disease occurred chiefly in the spring and early summer months, but might occur at other seasons. The usual course was complete recovery, but death was not uncommon, either by terminal infection or by sudden collapse during the time when the child was weak. He had collected fifty-three references from medical literature.

Operative Treatment of Infantile Paralysis.

Mr. ROBERT OLLERENSHAW, in an address on the operative treatment of infantile paralysis, said that those who had not followed the progress of orthopaedic surgery during the past fifteen years would be astonished at the change in the treatment of the residual paralyses of anterior poliomyelitis. Whereas these conditions were formerly looked upon simply as cases for special boots, irons, and the like, there were now many well established surgical procedures directed to the improvement of function in the paralysed limbs. The speaker emphasized the need for a proper period of correct splinting to afford complete relaxation of the over-stretched paralysed muscles in addition to suitable physio-therapeutic measures before any operation was undertaken. Tendon transplantation, with its indications, technique, pre- and post-operative treatment, and effects, was fully discussed. The speaker showed lantern slides illustrative of transplantation for talipes valgus, varus, cavus, and paralysis of the quadriceps. Slides were next shown to illustrate the value of arthrodesis of the shoulder-joint in paralysis of the upper arm group, of subastragaloid arthrodesis for stabilization of paralysed foot, of subastragaloid arthrodesis, combined with a "bone stop," for dangle foot, and of bone plastic operations for talipes calcaneo-cavo-valgus. Illustrations of cases of the same condition, showing astragalectomy with backward displacement of the foot by Whitman's method, were next shown. In conclusion, the speaker urged again that each case should be taken as an entirely separate problem and carefully studied in all its aspects before any form of operative measure was undertaken, and, further, that most cases of residual paralyses were capable of acquiring improved function as the result of one or other of the methods demonstrated.

NATURAL AND ARTIFICIAL CREAM IN INFANT FEEDING.

At a meeting of the Maternity and Child Welfare Group of the Society of Medical Officers of Health on January 21st, Dr. HAROLD SCURFIELD (Vice-President) in the chair, Dr. REGINALD JEWESBURY opened a discussion on the use of cream (synthetic and otherwise) in infant feeding.

Dr. Jewesbury said that fat was one of the most difficult and important constituents of the infant's diet, and that nearly all prepared infant foods were deficient in this constituent. The fat chosen might be natural cream, or other fat, but natural cream possessed the disadvantage of uncertain composition, depending on whether it was separated or centrifugalized cream, as well as the ordinary inconveniences associated with cow's milk. He had found emulsified fats more satisfactory in use, and recommended a 50 per cent. emulsion containing cod-liver oil. The introduction of such a fat must in all cases be gradual. "New Zealand cream" was an example of such an emulsion; it was made from a recipe carefully compounded by the director of infant welfare in New Zealand, and was intended for use throughout that country. It was manufactured in a New Zealand Government factory, and Dr. Jewesbury had found it most satisfactory in use, readily assimilable, sterile, and keeping indefinitely, containing the vitamin intact, and having the high caloric value of 180 per oz. The composition was 50 per cent. fat; two-thirds of this fat was animal oil, including fresh New Zealand butter and cod-liver oil, and one-third vegetable oil, mainly pea-nut oil; sugars, mainly dextrose, and a little lactose, made up 40 per cent. The addition of the pea-nut oil was found of great assistance in promoting the digestibility of the animal oils. Whether this particular cream appealed to people or not, he strongly advocated the use of some

such product of uniform content in infant welfare work throughout the country.

Dr. E. A. BARTON summarized the process of the digestion of fat and reminded members that the digestibility of fats was very variable and was in inverse ratio to their melting points. Although human and cow's cream seemed comparable in this respect, the infant had difficulty at first in taking a milk mixture containing cream in similar proportion to breast milk. He believed that artificial creams should only be used when clean cow's cream was unobtainable. During the late war this had been the case in poor districts, and he had accordingly designed a synthetic cream which was cheap, clean, readily assimilable, and which, in contrast to the early synthetic cream of Dr. Eric Pritchard which he had previously used, contained the fat-soluble vitamin A. With help from Dr. Hampshire a cream had been derived from the emulsification of beef suet (of which owing to a higher melting point the digestibility was less than that of butter fat, but only to a matter of 4 per cent.), and this they had found was readily tolerated by infants; the fat content was 25 per cent.

Dr. DONALD PATERSON thought that synthetic creams were an unnecessary complication of ordinary cod-liver oil emulsions. People erred in exaggerating the chances of too little fat being given; the curds in infant stools were nearly always fat curds. Infants suffering from this condition were typically those who developed summer diarrhoea. The fat tolerance of the infant was easily overstepped, and as fat was slow in leaving the stomach it was often, if given in excess, a cause of vomiting when the next feed was given. The vitamin content of ordinary cream varied greatly and was liable to be deficient in winter. He believed in giving all children cod-liver oil for its vitamin content, and this was the practice at Great Ormond Street. The psychology of the mother was a factor in whether the child accepted fat or not. He advised giving cod-liver oil before instead of after three of the daily feeds.

Dr. J. F. HAINES described the process of fat digestion, and stated that while the fine state of emulsification of fat in breast milk contributed to its ready digestion by the infant, it was possible that each kind of fat required its own enzyme, and that foreign fats given to the infant suffered on this account. It was recognized that it was necessary to approximate as far as possible to breast milk in composition and in ratio of constituents, and he thought that for this reason milk fat in the form of cream or butter was better than any vegetable or other animal fat. He had tried many synthetic creams, but for some years now had advised the addition of fresh butter to infant feeds in a poor district where expense and simplicity had to be considered, and his results had been extremely satisfactory. The percentages were easily calculated—a quarter of a teaspoonful of butter in a three-ounce feed raised the percentage of fat 1 per cent. The important point was to introduce fat into the feeds slowly and gradually, remembering the infant's tendency to intolerance, and if necessary giving alkalis and biliary stimulants as well. Cod-liver oil given in a similar manner was the best substitute for milk fat.

Dr. W. COX followed with some statistics of his results from the administration of "vitoleum cream," and Dr. FLORA SHEPHERD dealt with the possibility of infection from cow's cream or butter. Dr. MARGARET AIDEN quoted a series of letters from various medical officers to whom she had written asking for information regarding their practice in the use of fats; cod-liver oil seemed to be the fat in general favour. Drs. GREIG, CHODAK GREGORY, KIDD, EMSLIE, and NASH also contributed remarks, and the CHAIRMAN, in closing the discussion, referred to the pasteurization which is, or used to be, the natural procedure in the making of Devonshire cream and Devonshire butter; such butter and cream might be inferred to be sterile.

Dr. JEWESBURY briefly replied to the discussion, and it was decided to consider the subject of cream further by appointing a subcommittee, which would report to the Secretary of the National League for Health, Maternity, and Child Welfare in due course.

Reviews.

FRACTURES AND DISLOCATIONS.

THE importance which the treatment of fractures acquired during the war has been, to a great extent, maintained owing to the increase in the frequency of such injuries which has followed the multiplication of motor cars and lorries and motor cycles. These injuries are being treated all over the country, in cottage hospitals as well as in the larger institutions in the great towns. It is not surprising therefore that the first edition of the book on *The Treatment of Fractures in General Practice* by MAX PAGE and BRISTOW, which we reviewed two years ago (JOURNAL, January 5th, 1924, p. 17) has been sold out. We are glad to see that the second edition has been extended to include the treatment of dislocations.¹ This new chapter has all the good qualities which we found in those on fractures. In the section on dislocation of the hip the authors brush aside most of the elaborate descriptions, classifications, and manœuvres of the textbooks, and state that practically two kinds of luxation—namely, anterior and posterior—are met with, and two sets of symptoms and of manœuvres for reduction are all that need be considered in practice. Other dislocations are discussed in a similar practical spirit. There are more illustrations in this than in the first edition, and the number of pages is necessarily increased, but despite this the price remains unaltered. A rather fuller index would be a boon to the busy man who is looking for advice on some one point.

Professor PIERRE DELBET is well known as an authority on the treatment of fractures, and although he contributes only a preface to the book on the subject just issued in Paris² has former pupils who have written it expound almost exclusively his opinions and practice. It is therefore one of a greater importance than the names of its authors might at first sight imply. Professor Delbet tells us that in France (as in England) there has been a tendency to neglect the study of these injuries; that dislocations were not fashionable; and that those who were interested in fractures were attracted chiefly by plating and analogous methods, which really are only applicable to certain special cases. In the 187 pages devoted to the "orthopaedic" treatment of fractures the appliances and methods of Delbet are described. These are not so much ambulatory as intended to secure early active movements of the joints above and below the sites of fractures, and so to prevent or remedy muscular atrophy and stiffness. For fractures of the femur Delbet's combination of plaster-of-Paris and steel spring extension, leaving the knee and hip free, is fully described and illustrated, but we find no references to the ice-tongs method of direct extension of the lower fragment such as has given good results in the treatment of gunshot fractures, while Codivilla's and Steinman's methods of securing the same end by nails or pins are damned with faint praise. Pott's—or, as it is called in France, Dupuytren's—fracture receives brief notice in this section. As it is a fracture into a joint it is held that unless complete reduction can be obtained open operation is preferable to orthopaedic methods, and this applies to other fractures about the ankle. The technique of open operations in this region is very fully described. Much space is devoted to the open (*sanglant*) treatment of fractures, and here the methods of Lambotte receive a good deal of notice as well as Delbet's and other more or less complicated apparatus for fixation of fracture of the neck of the femur by means of screws.

The chapters on luxations are in general adequate, but we cannot pass over without comment the unqualified

condemnation by M. Raoul Monod of Kocher's method of reduction of dislocations of the shoulder, a modification of which is generally employed in this country, and is recommended in the book by Max Page and Bristow, the second edition of which is noticed above. The method recommended as the only good one ("*la seule bonne*") would, it appears to us, in many circumstances be inapplicable. Professor Delbet warns the reader that he will find neither bibliography nor discussion. It should also be noted that he will find no reproductions of radiograms and very little attention to diagnosis; but for those who wish to learn the methods which are favoured by a master of his art we can recommend this book.

MURDER AND THE DEFENCE OF INSANITY.

THE *Trial of Ronald True*³ has been added to the series of Notable British Trials. The volume is edited by Mr. DONALD CARSWELL, a barrister-at-law, whose father, Dr. John Carswell, an authority on mental disease, gave evidence before the Committee on Insanity and Crime set up by Lord Birkenhead as the result of the controversy about True's reprieve. Of these advantages the author has made good use in the admirably lucid introduction which precedes a verbatim report of the trial.

The trial of Ronald True possesses the usual sordid details of lust and callousness, but it differed from other trials of the type because it revealed in sharp contrast the positions taken up by the legal and medical professions in cases where insanity is raised as a defence to a charge of murder. The circumstances of True's reprieve were distinctly unfortunate, and we are indebted to Mr. Carswell for setting out those facts which, had the newspaper press devoted its columns to their correct presentment, would have given the general public a truer appreciation of the legal and medical aspects of the trial, instead of—even to this day—a garbled idea that True was reprieved because of "influence in high circles," whereas Jacoby (a hotel porter under sentence for the murder of Lady White at the time of True's reprieve) was executed because he had none.

True's medical history, as described by Mr. Carswell, reveals clearly a condition of mental disorder aggravated by the morphine habit. In all likelihood it was only because his family did not move to have him certified until he actually disappeared from them to enter upon the final debauch in which he committed murder that he was not an inmate of a lunatic asylum long before. Where the issue is one of insanity, both the prosecution and the defence can usually find medical witnesses having opposite opinions, but the prosecuting counsel in the True trial was faced with the fact that medical opinion as to True's mental condition tended all one way. This explains a somewhat singular feature of the trial: that, although insanity was the issue, no medical witness was produced by the Crown to rebut the array of medical evidence called by the defence. Sir Richard Muir, the counsel for the Crown, relied entirely upon the M'Naghten rules: briefly he set out to prove, and did in fact prove, to the satisfaction of the jury, that True knew what he was doing when he murdered his victim, and knew that what he was doing was wrong. This epitomizes the legal doctrine of responsibility in murder cases where the defence is one of insanity. The jury brought in a verdict of wilful murder, and the True case illustrates the circumstance that a man may know what he is doing and that what he is doing is wrong, and so be legally responsible for his acts—and yet be insane by medical standards. The Home Secretary (who was then Mr. Edward Shortt) was bound by Act of Parliament to appoint a committee of alienists to inquire into the sanity of the condemned man, and, further, was bound to respect that committee's finding of insanity and reprieve True because, by the Common Law of England, an insane person must not be hanged. The reason for this ancient humane rule was stated quaintly

¹ *The Treatment of Fractures and Dislocations in General Practice*. By C. Max Page, D.S.O., M.S.Lond., F.R.C.S., and W. Rowley Bristow, M.B., B.S.Lond., F.R.C.S. Second edition. Oxford Medical Publications. London: H. Milford, Oxford University Press. 1925. (Demy 8vo, pp. xiii + 273; 148 figures, 12s. 6d. net.)

² *Traitement des Fractures et Luxations des Membres*. Par Jacques Delbet, Ch. Girard, P. Mornard, Raoul Monod. Préface du Professeur Delbet. Paris: Masson et Cie. 1925. (Cr. 8vo, pp. vii + 464; 247 figures, 25 fr.)

³ *Trial of Ronald True*. Edited by Donald Carswell of the Middle Temple, Barrister-at-Law. Notable British Trials. Edinburgh and London: W. Hodge and Co., Ltd. 1925. (Demy 8vo, pp. x + 295. 10s. 6d. net.)

by Sir John Hawles, Solicitor-General in the reign of William III, in one of the State trials, to be: "That it would be inconsistent with humanity and inconsistent with religion to make examples of such persons as being against Christian charity to send a great offender 'quick,' as it is styled, into another world when he is not of a capacity to fit himself for it."

It is, however, a commonplace of medicine that there are degrees of insanity, and the further question: "Do you agree with the jury's finding that True, though insane, knew what he was doing and knew that what he was doing was wrong—that is, possessed a sufficiently guilty mind to be held responsible and hanged?" was never asked of the committee. Whether the Home Secretary had power to ask this question, and whether the committee would have felt justified in answering it, is not for us to decide, but it would have gone some way towards bridging the divergency between the medical and legal positions. It was Lord Brougham who once quoted the striking story of the patients confined in York Asylum. They discussed the case of the incendiary Martin when he was about to be tried for setting York Cathedral on fire, and the conclusion which they reached was: "He will be all right for he is one of us, so the law will take no notice of him." And so, it may be asked, if a certified lunatic, legally responsible if tested by the M'Naghten rules, murders an asylum warder or doctor, ought he not to be hanged? Clearly, the question of legal responsibility and the question of insanity are distinct from one another. The medical profession has never said "an insane man ought not to be hanged for murder." This is not a medical dictum, but it is an axiom of the Common Law of England.

The appendixes render the book invaluable for reference purposes. They contain the questions framed by the House of Lords after the assassination by M'Naghten of Sir Robert Peel's private secretary in 1843, and the answers of the judges thereto—which are now known as the rules in M'Naghten's case. Mr. Carswell devotes a portion of his introduction to an illuminating analysis of their legal bearing. The appendixes include also a report of the proceedings in the Court of Criminal Appeal on True's appeal, the Home Secretary's justification before the House of Commons of his act in reprieving True, and the report of the Committee on Insanity and Crime over which Lord Justice Atkin (to whom the book is appropriately dedicated) presided. Incidentally, it might be mentioned that this committee expressed substantial agreement with the memorandum on criminal responsibility submitted to it by the British Medical Association. In its recommendations the committee said: "It should be recognized that a person charged criminally with an offence is irresponsible for his act when the act is committed under an impulse which the prisoner was by mental disease in substance deprived of any power to resist. It may require legislation to bring this rule into effect. Save as above, the rules in M'Naghten's case should be maintained." This recommendation, it may be remarked, was strongly disapproved by the legal profession as a whole.

Lord Justice Atkin's committee further expressed the general opinion that "to the insane person justice is done," but made no reference to the question whether in the interests of the public a murderer of the type of True, though insane, yet possessed a sufficiently guilty mind to be made to suffer the legal consequences of his crime. So future juries in murder trials where insanity is raised as a defence will still be asked whether the prisoner is sane enough to possess a guilty mind, and, having answered in the affirmative, and the prisoner having been sentenced to death, the Home Secretary, by Section 2 (4) of the Criminal Lunatics Act, 1884—"if it appears either by means of a certificate signed by two members of the visiting committee of the prison in which the said prisoner is confined, or by any other means, that there is reason to believe such prisoner to be insane"—will continue in such a case to appoint medical experts to examine the prisoner and report on his sanity.

The book is well worth perusal by all interested in so delicate a medico-legal issue as that raised by the trial of Ronald True.

A GERMAN TEXTBOOK ON TROPICAL MEDICINE AND HYGIENE.

WHEN three authors of repute in the world of tropical medicine collaborate in writing a book on their specialty readers naturally expect a high standard. Such expectations are not completely fulfilled in the new edition of the diseases and hygiene of warm climates⁴ by Professors RUGE, MÜHLENS, and ZUR VERTH. Their aim has been to include what will be useful for the practitioner, and therefore diagnosis and treatment are the chief ends in view. Since rational treatment is based on pathology, this aspect of the subject merits more than the few lines of small print which is all that is given to many of the diseases. With the exception of the binding, which is flimsy, the get-up of the book is very good, the print is clear, misprints almost absent, and the illustrations, with few exceptions, excellent. The coloured plates at the end, taken from works such as the *Handbuch* of Mense and of Kolle and Wassermann, are very good.

The text might be better balanced. In the first section, on tropical hygiene, only housing is adequately dealt with. The article on the blood, though short, is sufficient and well expressed, and contains an excellent section on the pathological conditions and artefacts to be distinguished from malarial parasites. As regards malaria, we note that the subtertian parasite is called *Plasmodium immaculatum*, and that *P. praecox*—the parasite of avian malaria—is given as a synonym, while *P. falciparum* is not. Dysentery is exceptionally well treated, and a sound attitude is taken with regard to diarrhoea associated with the presence of flagellates.

As examples of inequality we may say that seven pages are allotted to typhus, five to *ulcus tropicum*, two to syphilis, alastrim half a page, and five lines to tabes, general paralysis, and mental diseases together; treatment of undulant fever by serum and vaccines is dismissed in a line as worthless. Under tuberculosis the information given is little more than a list of places in which the disease is met with; there are no statistics and nothing as regards its characters, the reasons for prevalence, and so on. The article on sprue is also poor and practically disregards the work done on this disease during the last three years.

The section on schistosomiasis is fairly full and the pathological anatomy clearly described, but the part dealing with cestodes is weak. Neither echinococcus nor any of the taeniae are described at all. In fact, *H. nana*, *H. diminuta*, *Sparganum mansoni* and *Sp. prolifer*, relatively unimportant worms, are the only ones deemed worthy of notice in the text, and the reader is told to diagnose *H. nana* by "recognizing the scolices [sic] in the large oval eggs." The mode of liberation of *Dracunculus* embryos, as described by Professor Leiper, is not mentioned, but the time-honoured error of oral parturition is perpetuated. A great feature of the helminthological section is the series of diagrams by Professor Fülleborn illustrating life-histories and modes of conveyance.

Poisons are, on the whole, adequately dealt with. Exception, however, must be made of the vegetable poisons, the account of which is scrappy. Selection seems to have been made without any idea of relative importance. Lathyrism, atropicism, lacquer dermatitis, and poisoning by *Hippomane mancinella* only are described, whereas there are many other more important poisonous tropical plants of which not a word is said.

We have considered it our duty to mention these points, as this is a second edition, said to be completely revised. It contains much that is helpful, and the price is not excessive; moreover, it is written in clear language, interesting to read, so that future editions are certain to be called for, when by revision, a little amplification, and a few additions it will become a standard and will deserve high appreciation as a textbook on tropical medicine and hygiene.

⁴ *Krankheiten und Hygiene der warmen Länder*. Von Professoren Reinhold Ruge, Peter Mühlens, und Max Zur Verth. 2 vollständig umgearbeitete Auflage. Leipzig: Dr. Werner Klinkhardt. 1925 (Sup. roy. 8vo, pp. 491; 443 figs., 9 plates. Paper cover, M.30; bound, M.32.50.)

DISORDERS OF THE SYMPATHETIC NERVOUS SYSTEM IN HEMIPLEGIA.

THE occurrence in hemiplegia of changes of body temperature, of sweating, of blood pressure, etc., on the affected side has long been recognized, and Dr. JOSEPH PÉRISSEUX has made a valuable contribution to our knowledge of these changes in his recently published *Etude Clinique et Pathogénique des Troubles Sympathiques dans l'Hémiplégie*.⁵ Working in Professor Guillaumin's clinic at the Salpêtrière, he made a detailed study of a large number of cases of hemiplegia from various causes, with reference to the condition of the sympathetic nervous system. The monograph before us embodies the details of his researches and the conclusions which he has drawn from them.

Evidence of some degree of disturbance of the sympathetic nervous system is practically constant, and the author's first conclusion is that such disturbance is the direct result of the brain lesion and not simply a consequence of the loss of movement of the affected limbs. His cases came to group themselves into three types, and led him to distinguish in consequence three syndromes. The commonest he describes as the "syndrome hypothermique," and this is characterized chiefly by the occurrence on the paralysed side of a lowered temperature, lowered arterial blood pressure, and increased sweating.

Exactly opposite conditions prevail in the "syndrome hyperthermique," which is found to occur as a rule at the onset of hemiplegia and to pass rapidly into the "syndrome hypothermique." Occasionally, however, this second syndrome persists for weeks or months before finally passing into the first type; this delayed reaction the author terms the "syndrome hypothermique secondaire." The early hyperthermal syndrome he attributes to inhibition or paresis of the sympathetic system consequent upon the cerebral lesion, and he draws an analogy between this and the early flaccid stage of the motor hemiplegia. The later hypothermal state he regards as due to liberation of the activity of the medullary vegetative centres—a release phenomenon—and analogous to the spastic stage of paralysis of the voluntary muscles, though not corresponding exactly in point of time, the motor changes preceding the sympathetic. As a rule, therefore, changes referable to the sympathetic nervous system coexist with a lesion of the pyramidal tract, and vary in intensity directly with the degree of pyramidal disease. It appears, however, that extrapyramidal pathways are also concerned in the mechanism of sympathetic regulation, and from his pathological observations the author concludes that the corpus striatum plays an important part; the optic thalamus, on the other hand, is apparently not concerned in the mechanism. While some doubt may be felt as to his anatomical conclusions, and especially his postulation of a controlling pathway from the cortex to the corpus striatum, this careful record of investigations will well repay study.

OBSTETRICS AND GYNAECOLOGY.

THE first edition of Dr. BETHEL SOLOMONS'S *Handbook of Gynaecology* was published six years ago, and we are glad to welcome the second.⁶ It has been brought up to date in many directions and has been somewhat enlarged. Without pretending to be at all exhaustive, this book is yet a great deal more than a mere cram-book. It is written from a strictly practical point of view, and practitioners will find much simple lucid teaching to help them in the gynaecological work they may be called upon to do. Students will also find it useful for examination purposes. The book is now very well illustrated and two coloured plates have been introduced. The illustrations are practical and helpful, but we are not sure that those of Treadwell's operation for keeping the Fallopian tube patent by the introduction of catgut are among them; it seems doubtful whether the procedure will survive. This book

may be cordially recommended to students, and to practitioners who need a simple and short practical synopsis of gynaecology.

Dr. JESSNER of Königsberg has issued a small book upon the diagnosis and treatment of gonorrhoea in women.⁷ The subject is discussed systematically and well in the space of ninety-four pages, and there is a useful index at the end. There are no illustrations. Those who enjoy reading German will find this an instructive little book.

Professor FOTHERGILL'S *Handbook for Midwives and Maternity Nurses* is well known and requires no introduction to the profession. In the fifth edition,⁸ which has just appeared, the chapter on the artificial feeding of infants has been brought up to date by Dr. H. T. Ashby. In other respects the book is similar to its predecessor, and forms a very lucid and short introduction to midwifery for the particular public to whom it is addressed.

Dr. PAUL DALCHÉ of the Hôtel-Dieu has summarized a great deal of the modern knowledge and modern speculation with regard to what he calls *Maladies de l'Ovulation*⁹ in a monograph of 175 pages. Those who are interested in the subject will find that his views are suggestive, although perhaps there is no information which may not be acquired equally well in English textbooks. As the title is not exactly self-explanatory, it may be said that the range of subject-matter includes such diverse topics as experimental parthenogenesis, sterility, amenorrhoea, dysmenorrhoea, and "ovaritis." It is always stimulating to read even a familiar subject in a foreign language, as the point of view is generally somewhat different, and, in this respect, we cordially commend this little volume.

THE BIRMINGHAM SCHOOL OF MEDICINE
(1825-1925).

ON December 5th, 1925, in anticipation of the celebration of the centenary of the Birmingham Medical School, we published an outline of its history, and in the following issue we reported the ceremonies; the guests received a special copy of the *Birmingham Medical Review*¹⁰ containing a fuller history, compiled under the editorship of Dr. K. D. Wilkinson, who truly observes that a somewhat stormy past has been succeeded by a prosperous present: he looks forward to a great future for the school, which has, we may note, in several ways recently shown its desire to move with the times. The account we published in December will absolve us from following Dr. Wilkinson and his collaborators through the history they have compiled; but we may mention that the book is well illustrated by portraits of teachers and alumni, and members of the British Medical Association will be interested to find of how many of these Birmingham doctors it is said in the course of the biographical details about them that he was "a great worker for the British Medical Association."

To those who wish to obtain a fuller view of the origin of the school, the account of William Sands Cox and his connexion with it, by Professor J. T. J. MORRISON, prepared at the request of the Medical Committee of Queen's Hospital, will prove most interesting. The book¹¹ is also a centenary volume, and in it are described the vicissitudes through which the institution passed until it developed into the full flower of a university in 1900; the financial sacrifices made by the lecturers and others whom Cox succeeded in interesting in his projects; and the munificence of the Rev. Dr. Warneford and the troubles brought about by his insistence on an exclusively

Church of England complexion in a college situated in a centre of Nonconformity. From delicate hints and occasional anecdotes we obtain also an inkling of the jealousies and minor quarrels which from time to time delayed, but never stopped, the progress to university status. In the chapters on the Queen's Hospital it is noted that that institution holds a special place among the provincial hospitals of the country, in that its predominant purpose was the provision of clinical instruction for the medical students of Birmingham. The foundation of this hospital was of immense value in the development of the medical school. The subsequent progress of the school, after the decade in which its fortunes sank to their lowest ebb, was due partly to the new constitution prepared both for the college and the hospital by the Charity Commissioners in 1865, and partly to the foundation of the Mason College by the wealthy Josiah Mason. The era of Sands Cox ended in 1868, his intense conservatism having, as Professor Morrison points out, unfitted him for adaptation to the altered circumstances. But, as Professor Morrison points out in his final chapter, "The Last Phase," Sands Cox's relations with the Council and the professoriate remained more than friendly—even cordial, and his liberality to the college never varied. He died in December, 1875.

SHERRINGTON'S VERSE.

THAT a President of the Royal Society should have poetic imagination and write verse is not unknown, for a hundred years ago the President (1820-1829) Sir Humphry Davy set this example, and neurology would appear to be a factor of possible import, for Sir CHARLES SHERRINGTON, who has just put off the presidential robes, has published his long expected book of poems, *The Assaying of Brabantius and Other Verse*,¹² with a dedication to his contemporary neurologist and singer Henry Head. The "Assaying of Brabantius," which occupies almost half the volume, has a high moral and some fine lines. The eighteen shorter pieces, some of which had appeared in the *Oxford Magazine*, shed new lights on various aspects of life, grave and gay, and show a touch that charms, such as the concluding stanza of "Ifley," written in 1916—

Ere came the vesper bell to cease
the low sun, like a cloudy torch
trailing blood-crimson past the trees,
fired Ifley porch.

NOTES ON BOOKS.

DR. A. G. G. THOMPSON'S pamphlet entitled *Babies*¹³ deals with the care of a normal baby. It is clearly written, contains sound teaching, and several practical hints of value. It is questionable, however, whether, in a pamphlet intended for popular use, the addition of raw cream to the infant's feed should be advised, without insisting that the cream should be taken from tuberculin-tested cows. There are no diagrams or pictures. Very similar information and advice is given in a pamphlet *Our Babies*,¹⁴ by Dr. BUNDESEN, Commissioner of Health for the City of Chicago; it is set out in an entirely different manner. There is a brightly coloured picture of a bonny baby on the cover, and on every page are many little sketches and diagrams to attract the eye and impress the visual memory. The centre page shows in a diagrammatic way the solar spectrum extending between the sun and a naked baby exposed in the violet rays: a crude representation, but very convincing. Altogether the pamphlet is an excellent piece of health propaganda.

In his essay on the origin of dysentery¹⁵ Dr. HANNS GLEITSMANN comes to the conclusion that the chief factors in an outbreak of dysentery are a maximal surface warmth and a fall of the subsoil water. A combination of these two factors, he maintains, is indispensable for the development

of an epidemic. The essay is illustrated by numerous charts and tables of dysentery epidemics in Germany and foreign countries.

Mr. ST. GEORGE LANE FOX PITT'S work *The Purpose of Education*,¹⁶ of which we reviewed a cheap edition on November 7th, 1925 (p. 852), has now been revised and reprinted. The most important addition deals with the latest aspect of the currency question, certain popular fallacies being exposed.

In *Figs from Thistles*¹⁷ we have what the publishers very properly call "an incisive attack on modern democracy." Starting with the statement that the British are of all peoples the least fitted for pure or advanced democracy, and that it is this contention which he wishes to justify, Mr. WELBY makes a carefully reasoned plea for government by an *élite* of the nation. Throughout he commands our attention. How much or how little the reader may at the end find himself in agreement with the author depends on personal political bias, but that fact can in no way detract from our admiration for the trenchant manner in which the thesis is expounded. It is certainly a book to make the reader think, and it is a book to take up and read again.

PREPARATIONS AND APPLIANCES.

Enucleation of Tonsils.

THE instrument here illustrated has been designed primarily for use in enucleation of tonsils by the blunt guillotine by Dr. C. D. AGASSIZ (High Wood Hospital for Children, Brentwood), who describes it as follows:

The square-ended blade is fitted with a small piece of rubber sponge (1½ by 3¼ by 3¼ in. approximately, cut to the required shape, slit to receive the blade, and sewn on), and a small gauze bag made with a purse-string thread at the neck is slipped over the sponge at the time of operation and the thread pulled tight. The

other blade is covered with a piece of rubber tubing. The instrument is applied immediately after the enucleation of the tonsil—the sponge-covered blade to the tonsil bed and the other blade behind the angle of the jaw. A clear field for the removal of the second tonsil is then left, and when both are applied haemorrhage is prevented. Two instruments—right and left—are required for each operation. In emergency in case of secondary haemorrhage this instrument may also be useful.

The instrument can be obtained from Messrs. John Bell and Croyden, 50, Wigmore Street, London, W.1.

Ostelin.

The preparation "Ostelin" which we have received from Messrs. Glaxo is a highly concentrated preparation of the antirachitic factor which is present in cod-liver oil. The method of preparation is based on methods elaborated at Columbia University, New York. The antirachitic factor in cod-liver oil is known to be associated with the unsaponifiable fraction of the oil, and the methods used produce a preparation in which the antirachitic factor is in a two-thousandfold greater concentration than it is in crude cod-liver oil. For convenience of administration the active principle is sold in a glycerin solution, three drops of which form a single dose for a child. Experimental work with ostelin has shown that the quantity needed daily to prevent rickets in a rat is a few hundredths of a milligram. Clinical reports published by Messrs. Glaxo appear to show that three drops of ostelin three times a day were sufficient to produce a cure in cases of well marked rickets. The experimental and clinical results indicate that ostelin possesses the full antirachitic action of cod-liver oil. Ostelin should prove a valuable remedy for rachitic children who dislike the taste of cod-liver oil, or in whom the oil produces diarrhoea. The drug also will make possible a more intensive treatment of rickets than has hitherto been possible, since the equivalent of a large quantity of cod-liver oil can be administered daily without fear of digestive disturbance. Ostelin, as supplied for therapeutic use, is diluted so that three drops of the glycerin solution are equivalent to a teaspoonful of cod-liver oil. A bottle containing forty-five doses, which are the equivalent of about 6 ounces of cod-liver oil, is sold for 2s. 6d. The cost, therefore, of treatment with ostelin is only twopence a day.

SATURDAY, FEBRUARY 6TH, 1926.

VITAMIN DEFICIENCY.

THE two papers read before a recent meeting of the Section of Comparative Medicine of the Royal Society of Medicine (of which a report appears at page 239) bring out very clearly two of the most important directions in which our knowledge of vitamins is advancing.

Professor Drummond showed that one vitamin—namely, the fat-soluble antirachitic factor called vitamin D—had already been synthesized from the chemically pure substance cholesterol, and that we were within measurable distance of isolating it in a chemically pure form. This is a step forward of great importance, because it means that our knowledge of the nature of this vitamin is already more advanced than our knowledge of such substances as bacterial toxins and antitoxins or even insulin. There is therefore no justification for continuing to regard vitamins as hypothetical substances of a particularly obscure nature. The most remarkable fact about the recent advances in the isolation of vitamins is that they have been found to be substances of extraordinary potency; in the case of vitamin D the daily dose necessary for a rat is less than 0.002 mg. Figures such as this call to mind the internal secretions, which are the only other substances necessary to the body which act in quantities of this order.

The acquisition of exact knowledge of this kind concerning vitamins has led to the institution of quantitative experiments concerning their action. The early experiments on vitamins were qualitative in nature, and directed to ascertaining the distribution of these substances in foodstuffs. As was natural, the tests undertaken to determine their presence were made as short as possible, and vitamin-free diets were evolved which produced acute diseases in suitable animals within a few weeks. The diseases thus produced, such as polyneuritis, keratomalacia, scurvy, and fulminating rickets, are rarely met with in clinical practice in this country, and hence the importance of vitamin supply in clinical medicine has been underrated. The idea has spread that so long as such diseases do not occur people are receiving an adequate vitamin supply, and all is well. Professor Plimmer's experiments shatter this comfortable belief. He studied the effect of partial vitamin deficiency, and extended his experiments over months instead of weeks. He found that partial vitamin deficiency did not produce any of the fulminating effects mentioned above, which are clinical curiosities; but that it did produce a series of effects which are among the commonest complaints of civilized man. The chief effect of partial deficiency of vitamin B was intestinal atony, which produced stasis and intestinal toxæmia. Furthermore, Professor Plimmer found that to maintain a number of animals in full health the bulk of their diet needed to be composed of substances fairly rich in vitamin B. For example, the amount of wholemeal bread needed to protect a

pigeon from partial deficiency of vitamin B was no less than 75 per cent. of the total diet. These experiments at once suggest that the ordinary diet in this country is very seriously deficient in vitamin B, for white bread is the basis of our diet, or at any rate of the diet of the great bulk of our fellow countrymen, and white bread is devoid of any vitamins whatever. Professor Plimmer himself pointed out the large specific differences that occurred in the vitamin needs of animals—for example, the rat needed only one-third as much vitamin B as did the fowl. For this reason care must be taken in applying results obtained on laboratory animals to man. We know, however, that complete deficiency in any one of four of the vitamins (A, B, C, and D) produces the same effects in man as in animals, and therefore we have no justification in assuming that man is a happy exception in the animal kingdom, and can live in full health on diets that produce definite disease in a wide range of laboratory animals.

The subject is, of course, of immense practical importance. Professor Plimmer's experiments suggest that a large proportion of the chronic disorders of the alimentary tract from which our urban population suffers can be attributed to the deficiency of vitamin B in our diet, which we have produced by abandoning wholemeal bread and substituting the vitamin-free white bread. If Professor Plimmer's conclusion is justified it is obvious that every possible endeavour should be made to induce our population to change its habits and once more eat wholemeal bread. This change would involve a number of serious economic consequences, for the transport and keeping of wholemeal flour presents certain difficulties, and farmers are largely dependent on the supply of wheat "offal" for feeding purposes. The obvious present need is for research on a large scale, with as wide a variety of animals as possible. The cost of such a research is probably beyond any of our institutions, but it would be negligible in comparison to the enormous interests involved.

BIOLOGICAL STANDARDS.

IN concluding the notice of the Annual Report of the Medical Research Council for the year 1924-25 published a fortnight ago (p. 150) we promised to deal with the question of biological standards in a separate article. This promise we now fulfil. The report refers to the passing into law of the Therapeutic Substances Act, 1925, as a notable event in the year, and one which is of great importance to the progress of medical science, to the daily practice of the medical profession, and to the safety of the public. The Council has long sought to encourage research work at the National Institute and elsewhere on the accurate standardization of therapeutic substances whose potency cannot be assessed by direct chemical means. As long ago as 1916 the Medical Research Committee addressed by request a memorandum to Mr. Asquith's Government, in which it gave reasons for its conviction that the absence of any control of the kind now secured was "discreditable to our national position in the world of science and a source of grave danger to the community." The primary object of the Therapeutic Substances Act is, of course, to protect both patients and doctors by fixing standards for the strength and purity of complex substances like diphtheria antitoxin or insulin, or complex chemical compounds like salvarsan.

It is satisfactory to reflect that much of the research

work carried out in this country on biological standards and the methods of biological assay has already borne fruit, and that the new Act will immediately become fully applicable to several important substances for which methods of assay have already been worked out and standard units accepted. For some years past the staff of the National Institute has been exercising functions on a voluntary basis or by special arrangements with other Government departments, some of which, under the new Act, may become a statutory duty. For example, the Standards Department of the Institute, under Dr. Dale's general supervision, has continued to test every batch of salvarsan for freedom from toxicity and for therapeutic potency. Dr. Hartley's work on diphtheria antitoxin also promises to be particularly useful in connexion with the requirements of the new Act. He has prepared a standard preparation of diphtheria antitoxin, and the regular issue of samples of this to manufacturers and institutions concerned with the testing of the serum in this country has already begun. This is as yet the only serum for which a standard and a method of assay have been accepted by international agreement under the auspices of the Health Committee of the League of Nations.

Under the auspices of the Health Committee of the League of Nations two international conferences have been held to discuss the possibility of providing stable standards of reference and agreed methods of biological assay for pituitary extracts, insulin, digitalis and other heart tonics, thyroid gland preparations, salvarsan and its analogues, male fern and other anthelmintics, suprarenal preparations and adrenaline, for ergot, and for preparations used for their vitamin content. The second of the two international conferences was held at Geneva early in September, when Great Britain, France, Germany, the United States, and five other nations were represented. Definite agreement was reached with regard to the first seven of the nine items above mentioned, and provision made where necessary for the preparation and preservation in some State institution of an international standard of reference.

Great Britain has already assumed the responsibility for insulin, and at the request of the international conference the National Institute accepted the duty of preparing and keeping the international standard of reference. A large supply of insulin was collected, and converted into the form of a dry, stable hydrochloride.¹ This material, after purification by repeated precipitation as a picrate and reconversion into the hydrochloride, was forwarded to the Insulin Committee of the University of Toronto for determination of its activity in terms of the current unit as defined by them. Simultaneous determinations were made in the National Institute and by three other laboratories in the United States of America and this country. The results from these various institutions varied only from 8.4 to 8.8 units per milligram of the dried preparation. The international conference therefore accepted the recommendation of the Toronto committee that this preparation, preserved at the National Institute, should be the international standard for insulin, and that one milligram thereof should be taken to contain eight units of insulin. Samples of this standard have already been supplied from the Institute to the responsible authorities in sixteen countries.

INCOME TAX: THE THREE YEARS' AVERAGE.

A good deal of prominence has recently been given in the general press to a decision by the House of Lords in the case of *Whelan v. Henning* against the contentions of the Board of Inland Revenue. Captain Henning was in possession of some shares in a foreign company the dividends on which were liable to assessment on the basis of the three years' average. In the year in question the shares produced no dividend, and he claimed that therefore there was no income assessable, and that the assessments made should be discharged. The unanimous opinion of all the judges who heard the case at its various stages—as well as of the local commissioners who first heard it—was that that view was correct, being the logical outcome of a fairly recent decision in the House of Lords in the somewhat similar case of *untaxed interest*. Captain Henning, therefore, is relieved from income tax in respect of his foreign dividends when the income is *nil*, and will also—unless, of course, some alteration be made in the statute law—be able when future dividends are received to include the *nil* in the three years' average, thus drawing some fiscal consolation for the temporary setback in his income from the shares.

The technicalities of the argument, with its wearying references to schedules, cases, and sections of the various Acts of Parliament, we are content to leave to others, but there are one or two points of a more general character which will repay attention here.

In the first place, it is a striking commentary on the extraordinary complexity of our income tax laws that a simple point of this kind can be brought to the courts to reverse in 1926 a practice that seems to have been unchallenged since the statutory basis of assessment was laid down in 1842. No doubt the prolonged persistence of an erroneous view is largely attributable to the heavy cost of litigation—apparently the Inland Revenue Department in this case pays the piper, or perhaps we should say that the country pays the piper though the department called the tune; but in either case it is strong confirmation of the contentions put forward by the legal and accountancy professions that the income tax laws urgently require some simplification.

The Lord Chancellor was careful to point out that the decision given did not deal with assessments in respect of business or professional profits, though, of course, he did not say that the decision could not be so applied. If it can the matter has a somewhat serious aspect for such taxpayers as may not be liable to a complete loss of profits, because trade fluctuations sometimes result in business losses, and to give effect to such losses twice over—one to discharge an average assessment and again as components of future averages—would tend to throw a greater burden on other classes of income-tax payers.

The *Whelan v. Henning* case may possibly prove to be another nail in the coffin of the three years' average system, which no doubt facilitates the preparation of Budget forecasts of revenue, but is very far from ideal in many respects. A basis which would render a man liable to pay tax on what he had recently received would in many ways be preferable to a system which constructs an artificial assessment when there is no such income out of which the tax can be paid. The latter possibility has been removed as regards income in the form of dividends from abroad

¹ In this connexion a paper by Dr. Dale and two of his collaborators published by us (*BRITISH MEDICAL JOURNAL*, 1925, vol. ii, p. 1102) may usefully be consulted.

or of interest at a heavy cost in legal expenses. We suggest that when the next Finance Bill is before the House of Commons all classes of income should receive equitable and identical treatment, and that a promise from the Chancellor of the Exchequer that a determined effort should be made to grapple with the task of simplifying the present legal chaos of Acts, schedules, leading cases, and the rest of the present cumbrous machinery, would provide some hope of better things to come—at any rate for the next generation of taxpayers.

EDINBURGH MEDICAL FACULTY BICENTENARY.

THE University of Edinburgh is arranging to celebrate 200 years of its existence in June, 1926. The details of the celebration have not yet been arranged, except as regards a resolution on the part of the Senatus and University Court that this should take place before the students leave for the long vacation. As is generally known, the Brethren of the Guild of Surgeons and Barbers, which had existed prior to 1505, in that year obtained a charter of incorporation from the town council of Edinburgh, which included the gift once in the year of "ane condampnit man efter he be deid to mak anatomie of," and the teaching of anatomy has continued in Edinburgh without interruption since that time. This teaching of anatomy also included surgical instruction. The Tounis College, which gradually developed into a university, was founded originally under a charter granted by James VI in 1583, but this instruction covered only the subjects of theology, philosophy, and the humanities. By the year 1670 the leading physicians of Edinburgh, including Sir Robert Sibbald, Sir Andrew Balfour, Sir Archibald Stevenson, Dr. Archibald Pitcairn, and Sir James Burnet, moved by the desire to reform medicine, set themselves to lay out a physic garden and to obtain a charter for the institution of a College of Physicians. The charter was granted in 1670, and the Royal College of Physicians, among its other activities, issued an *Edinburgh Pharmacopoeia* in 1699. By 1676 the physic garden had been prepared and a professor of botany had been appointed, and in 1713 James Crawford was nominated professor of chemistry and medicine. Sir Robert Sibbald, Archibald Pitcairn, and James Halket had already been appointed professors of medicine by the town council as early as 1685, but it does not appear that they instituted any regular course in this subject. Chiefly as the result of the activities of Pitcairn, the yearly demonstrations of anatomy by the Incorporation of Surgeons were greatly improved about the year 1702, and by 1705 Robert Eliot was chosen by the incorporation as "public dissector," and received from the town council a salary of £15 per annum. Eliot was thus the first "professor of anatomy" in the Tounis College and the earliest professor of this subject in Britain. In 1708, at his request, Thomas Drummond was conjoined with him in the post, receiving half the salary! Eliot was succeeded in 1717 by John M'Gill, but two years later he and Drummond resigned their posts in favour of Alexander Monro (primus). Monro was elected by the Edinburgh Town Council "Professor of Anatomy in this City and College," the yearly salary of £15 being continued to him, and his appointment in 1722 being confirmed for life. Monro was the first to give an eight months' course of instruction in anatomy, surgery, and physiology, and this formed the virtual beginning of the Edinburgh Medical School, so far as students from places outside the city were concerned. In the year 1720 the anatomy class included 57 students, and the number continued to rise till eighty years later it was being attended by over 400, drawn from all parts of the known world. In view of this it was deemed desirable to

add the teaching of other subjects required in medical practice, and in the year 1726 Andrew Plummer and John Innes were made professors of chemistry and medicine, Andrew Sinclair and John Rutherford professors of medicine and institutes of medicine, and Joseph Gibson professor of midwifery. It would seem, therefore, that a definite medical faculty was first constituted at Edinburgh in 1726. It appears that the town council regarded their college from the first as entitled by its charter to grant degrees, and there is evidence that the degree of M.D. was granted as early as 1705, David Cockburn having received the degree of M.D. from Edinburgh in that year. The privilege of licensing persons to practise medicine in Edinburgh was, however, jealously guarded by the Royal College of Physicians, and it appears at first to have been necessary for those who graduated at the Tounis College to apply to the Royal College of Physicians for licence to practise in the city. After the establishment of the medical faculty, however, in the Tounis College, which now began to be called the University of Edinburgh, it would appear from the records of the Royal College of Physicians that the Edinburgh graduates who intended to practise in Edinburgh often allowed several years to elapse between the date of obtaining their degree and their application to the College of Physicians for licence to practise. Although the beginning of the Edinburgh Medical School was gradual, a very definite step was taken in 1726, and it is therefore natural that the university should celebrate the bicentenary of the medical faculty in the present year.

PROTECTION OF X-RAY WORKERS.

WE have referred repeatedly to the important question of the protection of x-ray workers since the formation in 1920 of the X-Ray and Radium Protection Committee, under the chairmanship of Sir Humphry Rolleston. The National Physical Laboratory was represented on this committee, and gave the utmost possible support by advice and practical investigations; as the result of these experiments and the collaboration of distinguished radiologists, two reports were issued.¹ Dr. G. W. C. Kaye of the National Physical Laboratory opened the discussion on the protection of x-ray workers in the Physics Section of the International Congress last July,² and the foreign delegates were so deeply impressed that they arranged for copies of the proceedings to be circulated to each of the countries represented, with a view to establishing an international standard of safety. From the earliest days British manufacturers have most loyally supported the decisions of the Protection Committee, sometimes at very great inconvenience, certain designs of apparatus having to be scrapped and financial loss sustained. As a direct result of the weight of the protective material found to be necessary the British apparatus inevitably became heavier, less adaptable, and possibly less flexible, but the cost has relatively increased but little, and not more than is required to cover the expense of the additional protection found to be necessary with the use of higher voltage apparatus. Unfavourable comments on British apparatus have lately been made by a hospital committee, the allegation being that it is cumbersome in form, inadaptable, and costly as compared with the apparatus supplied by certain foreign firms. While France, America, and the Scandinavian countries, following the lead of Great Britain, have taken great care to ensure protection for the x-ray worker, this has not hitherto been the case in Germany, from which country the apparatus for the hospital in question was being ordered. There seems a possibility that the safety of the x-ray worker may be sacrificed on the altar of economy

¹ BRITISH MEDICAL JOURNAL, 1923, vol. i, p. 389.

² *Ibid.*, 1925, vol. ii, p. 72.

in some cases, and this is a danger to which hospital committees should be alive. It is perhaps not generally known that the Board of Trade has interested itself in this question of protection, and has now included certain diseases caused by exposure to x rays and radium in the schedule of dangerous occupations of the Workmen's Compensation Act, 1906. It seems likely also that insurance companies will soon require information about this question, and any public body will incur considerable risk in purchasing apparatus which does not in every particular comply with the requirements of the X-Ray and Radium Protection Committee."

STATISTICS OF CANCER IN DIFFERENT TRADES AND PROFESSIONS.

THE Medical Research Council has issued a special report (No. 99)¹ on the incidence of cancer in males engaged in different occupations. Hitherto the cancer death rates in relation to occupations have, except in a few instances, been considered without distributing the cases according to the part affected. The occurrence of cancer in special parts of the body associated with definite occupations (for example, cancer of the scrotum among chimney-sweeps) suggested that the examination of the incidence of cancer in different occupations, distributed in relation to the parts affected, might give further information as to the wider influence of substances already recognized as harmful, or might even disclose other injurious substances. The report is founded upon an offer of the Registrar-General to afford facilities of access to certain documents relating to cancer and sarcoma. The facts codified in the Registrar-General's office for three years (1910-12) included in the case of cancer, in addition to sex, age, and specific trade, the site of the disease. In this way the Council had access to 46,118 cards relating to male deaths from malignant disease, and on this material a survey of the relation of cancer (excluding sarcoma) to occupation was undertaken by Dr. Matthew Young and Mr. W. T. Russell of the National Institute for Medical Research, in collaboration with Dr. John Brownlee, director of statistics, Medical Research Council, and Dr. E. L. Collis, professor of preventive medicine in the University of Wales, the two latter being members of the Council's Statistical Committee. The Council points out in a preface that the best way of treating such material as was thus provided is still a matter of discussion among statisticians, and gives a warning to the reader that the investigation of cancer statistics is a difficult matter, upon which wide differences of opinion exist between competent statisticians. The appeal of the report is therefore limited, for it will mainly interest trade statisticians; for this reason we depart from our usual custom of analysing the report section by section, and give here only the paragraph in which the results of the investigations are summarized. "It must," it is said, "be acknowledged that, though confirmatory evidence has been obtained of some views already more or less generally accepted as to the close association of some types of cancer with exposure to particular risks incurred in certain forms of employment, for example, chimney-sweeps' cancer and mule-spinners' cancer, evidence in support of such a connexion between the nature of the employment and other forms of cancer, especially those localized internally, cannot be regarded as more than suggestive. In some occupations the excessive indulgence of habits like smoking and drinking, which the nature of the occupation permits or facilitates, appears to be the important predisposing factor and not anything inherent in the employment itself, while the incidence of syphilis in different occupational groups seems to have some association with that of lingual cancer.

In the data examined it is not uncommon to find, however, in occupations an excessive mortality from cancer in certain sites for which no apparent explanation can be found in the industrial risks. This emphasizes the fact that occupational risk is only one of several predisposing causes of cancer which are operative in different instances or under different circumstances, and supports the view that the discovery of any one specific factor is not likely to provide a solution of the complex problem of the origin of the disease."

MEDICAL MEN IN EARLY AERONAUTICS.

THE first social evening of this year took place at the Royal Society of Medicine on February 1st, with Sir StClair Thomson, the President, acting as host. In the course of the evening the Fellows and guests assembled in the Barnes Hall for a short lecture by Dr. F. J. Poynton on "The part taken by doctors in the early days of aeronautics." The President, in introducing the lecturer, said that it might be asked what a doctor had to do with flying, but there was nothing concerning human endeavour which did not interest the medical profession, because all human endeavour reacted upon the human body, which was the profession's charge. It was curious to think that in the lifetime of all those present there had been realized the dream of ages that man should fly—a dream which had found expression in the legend of Daedalus, who, with his son Icarus, made wings from feathers and wax and flew from Crete, Icarus falling into the sea. But apart from the medical aspects of aerostatics, medical men were interested in this as in other sciences for its own sake. It was true that the day had long since passed when a man could declare, with Bacon, that he took all knowledge to be his province. Medical men nowadays felt that it took all their energies to keep abreast of knowledge in things relating to their own profession, but at the same time they found other fields of science very engaging and did much work in them. It was noteworthy that William Gilbert, Luigi Galvani, and Thomas Young, who added so much to the knowledge of electricity, magnetism, and light, were all medical men. When Charles II founded the Royal Society, out of its 115 members the medical profession accounted for 25. Dr. Poynton, after a reference to the place of flying in fable, described the evolution of the balloon, and instanced the attractiveness which investigations along this line had had for some of the greatest intellects of the world—for example, Roger Bacon, Leonardo da Vinci, Swedenborg, and Joseph Priestley. He showed a number of old prints illustrating the famous exploits of Jacques Montgolfier and his brother in 1783 and subsequent years; it was said that Montgolfier purchased a French translation of Priestley's works, and thereby got his ideas for his balloon. Among the great Frenchmen of that day who were interested in aerostatics were Lavoisier the chemical philosopher, Marat the revolutionary, a man of no mean scientific attainments, and Pilatre de Rozier, who began as a medical student but turned to other branches of science, inventing a gas mask which was of great service to men working in the sewers of Paris, and presently made the first journey in a balloon across the French capital, perishing two years later in an attempt to make a similar journey across the Channel. The popular interest in this conquest of the air quickly spread to the United Kingdom, where the first person to ascend in a balloon was a Glasgow apothecary named James Tytler, a versatile man, who wrote a considerable part of the first editions of the *Encyclopædia Britannica*, but his Scottish caution forsook him when he married a lady who presently deserted him, and also when he became bitten with the balloon craze to such an extent that he was known as "Balloon Tytler." He succeeded in rising into

¹ Medical Research Council, Special Report Series, No. 99. An Investigation into the Statistics of Cancer in Different Trades and Professions. 1926. H.M. Stationery Office. Pp. 50. 1s. 6d. net.

the air, going up some hundred feet, but came down again "somewhat rapidly." Tytler eventually went to America, where he wrote a work on surgery in three volumes, as well as a book on the plague, in addition to editing a paper, and—a melancholy ending for one who had essayed flight—he was killed by falling into a clay pit. Dr. Poynton then described the deeds of Lunardi, the young Italian, who kept London agape for some time with his balloon ascents from Chelsea. The man who was entrusted with the task of filling Lunardi's balloon was none other than George Fordyce, F.R.S., physician to St. Thomas's Hospital and an excellent experimental chemist. Two other medical men who were greatly interested spectators on these occasions and who were also bitten by the craze were Dr. Jeffries of Boston, U.S.A., and John Sheldon, surgeon to the Westminster Infirmary and professor of anatomy at the Royal Academy. To honour Sheldon for his aeronautical exploits there was a triumphal procession in which he was the central figure. Among the many interesting prints the lecturer exhibited was a satirical cartoon of this period—the end of the eighteenth century—representing the Royal College of Physicians, then in Warwick Lane, being removed from the earth by a balloon and suspended in mid-air; the inscription stated that the College had remained three months in that position, and that the health of the country had never been better!

THE FOOD INVESTIGATION BOARD.

DURING the year 1924 the Food Investigation Board of the Department of Scientific and Industrial Research has been mainly concerned with inquiries and investigations, assisted by expert committees, into various problems connected with the freezing of beef, the use of cold and carbon dioxide in the preservation of fruit and in the preservation of eggs. The report for 1924¹ presents a summary of the work done in these various fields of research, and, in some instances, detailed and complicated accounts of the methods employed and the results of the investigations. Some of the work of the Board has already been noticed in our columns, notably the inquiries into "brown heart" and functional diseases of apples during cold storage, and some others of the investigations have already been published, either in the form of separate reports issued by H.M. Stationery Office, or in the *Proceedings* of the Royal Society, the *Biochemical Journal*, and other publications; but there is also much that is new in the report for 1924. The first section deals with the theory of freezing with a view to determining the changes that are liable to occur in freezing on a mass of colloid. Experiments were carried out with gelatin jelly, and led to the discovery that ice forms only on the external surface if the rate of freezing is slow enough, and only within the mass if the rate is high enough. With slow freezing the final state is a core of jelly, from which more than half the water is extracted to form a shell of ice. The practical conclusion is that in slow freezing of beef or mutton water separates out on the outer surfaces, and when the meat is thawed drains away, carrying with it a certain amount of nutritive material; but, when the freezing process is sufficiently rapid the separation of water is totally suppressed, and the thawed meat is in no respects different from fresh meat. In the freezing of eggs a still more curious result was obtained, for no change takes place in the frozen mass of the yolk if the temperature is not carried below -6°C .; but below that point the normal fluidity is lost, and a stiff pasty condition, which is permanent, results; although this change does not take place if the yolk is frozen very rapidly at very low temperatures and then thawed very rapidly. The experiments have an

important bearing on the preservation of eggs and the retention of their fertility for long periods. A full account of the investigation will be published in the next special report of the Food Investigation Board, now in the press. The preservation of fish was also the subject of inquiry during the year, but the experiments attempted at the Low Temperature Research Station at Cambridge failed, because there was no certainty as to the history and state of the material, purchased locally, before the experiment was commenced. The carrying out of experiments on fish preservation appears to have been practically impossible at an inland station, and a study of the problem can only be effected at a fishing port. Some very interesting researches were conducted on the preservation of fruit and vegetables. Various experiments for determining the course of respiratory activity throughout the life of apples are described in detail. Apples have, it seems, two life phases: that of growth, dependent on their existence on the tree; and that of senescence, when they have been gathered or dropped and lead an independent existence as isolated organs. In the former phase the respiratory activity decreases as growth increases; in the latter phase, on the other hand, respiratory activity increases rapidly soon after the apple has been gathered or drops, marking the transition from growth to senescence in what is termed a "climacteric" phenomenon. Interesting studies of this phenomenon in different kinds of apples and apples grown on different soils are detailed, especially in connexion with their storage in normal conditions, in cold storage, and in "gas" storage. The remaining sections deal with the chemistry of oils and fats, which is highly technical, and with engineering problems in refrigeration. The report generally is a fine record of scientific work, which is bound to have in time great importance in improving the methods and conditions under which food supplies are stored and preserved.

CONSTRUCTION AND MAINTENANCE OF HOSPITALS.

THE closing of the Bellahouston Red Cross Hospital, near Glasgow, after ten years of valuable work, has induced Sir George Beatson, who has been throughout connected with it, to review the methods adopted for the control of that hospital, and to discuss the application of the same principles to voluntary hospitals generally. The hospital was established in 1915, when material and labour were scarce. The simplest form of construction was therefore adopted—the bungalow type—each bungalow being connected by a long central corridor. The administrative and nursing quarters were erected in the grounds around the main building. This hospital of 1,200 beds was put up and equipped with the necessary annexes at a cost of £100,000. The Red Cross provided the hospital and equipment, paid all running expenses, and received a daily grant of 2s. 6d. for each patient to cover diet, drugs, and dressings. Applying these experiences Sir George Beatson considers that the one-story bungalow system based on the central corridor plan will probably be applied to hospitals in the future. After noting the great saving in staircases and lifts, he expresses the view that the regional distribution of auxiliary hospitals around central hospitals would be a great advantage. The financial arrangements of voluntary hospitals, he reminds us, were established to meet a condition of affairs that no longer exists; they should be modified to present-day requirements, but in such a manner as not to imperil the voluntary principle nor pave the way for "nationalization." The three points dwelt upon by Sir George Beatson are all of first-rate importance. The construction cost of the modern many-storied hospital is very high. The bungalow system is certainly cheap in first cost; but is it good and comfortable in running? We have heard of interminable passages and bitterly cold wards

¹ Report of the Food Investigation Board for the year 1924. London: H.M. Stationery Office, 1925. (Pp. vi+80; 6 plates, 41 figures. 3s. 6d. net.)

in wintry weather. Again, can the economical central kitchen provide hot meals to such widely spread wards? These are practical points that need elucidation. It may be possible to obtain records of experience from such a hospital as Bellahouston. The comment on the need for intercommunication between hospitals is timely, for it would undoubtedly be an improvement. The desirability of introducing the Red Cross system of finance into the voluntary hospitals is a more debatable proposition. At Bellahouston Government departments were responsible for all the patients, and failing the willing service of the Red Cross Society a Government hospital would have been established. Voluntary hospital patients are of many and various types, and that the hospital should be indemnified for all costs of maintenance and treatment in regard to patients for whom the State (whether through central or local authorities) is responsible is part of the policy of the British Medical Association. The payments received for such patients by the directors of the Bellahouston Hospital seem very low, even for such items as are stated to have been charged for.

RHEUMATIC INFECTION IN CHILDHOOD.

In a report to the Metropolitan Asylums Board on "Rheumatic infection in children" Dr. Gordon Pugh deals with the problem of the cardiac cripple. He quotes Dr. Askins's statement¹ at the last Annual Meeting of the British Medical Association that one-half of all cases of heart disease are of the rheumatic type. Dr. Askins said further that Dr. Carey Coombs had found in a prolonged investigation that two-thirds of the cases that came under his observation commenced between the ages of 5 and 15. Dr. Gordon Pugh shows that if these data are correct rheumatism in childhood is eventually responsible for one-twenty-fourth of all deaths—a figure far exceeding the contribution of all the commoner zymotic diseases. In the past insufficient attention has been paid to these matters by the health authorities; recently, however, there have been signs that public interest is being awakened. Dr. Pugh observes that as rheumatic fever has a great tendency to recur, and with each recurrence to add to the cardiac lesions, it eventually leads to the most marked cases of chronic carditis. Much must depend on the treatment the child receives in his first attack. Dr. Pugh holds that rest in bed is essential at least until the pulse rate is normal, but how long this should be continued afterwards is a matter for investigation. Sir Archibald Garrod believes that an organization which rendered it possible to give two or three months' rest in bed to all children with rheumatic fever would reduce very materially the severity and frequency of what was commonly spoken of as "heart disease" among the adults of the community. How to overcome the tendency to further attacks is, Dr. Pugh considers, a more debatable point. Whether the prevention of relapses depends on freeing the patient from the infection or on building up his resistance, treatment for a considerable period in hygienic surroundings appears to be indicated. Dealing with the question of accommodation, Dr. Pugh shows how difficult it has been to provide treatment of sufficient length either at children's hospitals or in general hospitals. Children at the guardians' hospitals have the advantage of a longer stay, and the opportunity of being transferred to one of the board's country hospitals or seaside homes. Dr. Pugh's report was prepared with a view to enabling the Metropolitan Asylums Board to arrive at a decision as to what further accommodation should be provided for cases of rheumatism in children. After consideration the board decided to adopt the suggestion contained in it to provide accommodation for sixty rheumatic

children at Queen Mary's Hospital for Children, Carshalton. A conference has since been held with the Minister of Health, and it is believed that his sanction will shortly be obtained. It will then become possible to make a careful study of the treatment of rheumatism on the most modern lines, and particularly by active immunization, which has already proved so successful in diphtheria and scarlet fever.

THE UNIVERSITIES AND PUBLIC HEALTH.

At a meeting of the Section of Epidemiology and State Medicine of the Royal Society of Medicine held on January 22nd, with Dr. E. W. Goodall in the chair, Professor E. W. Hope read a paper entitled "The influence of the universities on the advancement of the public health." Professor Hope pointed out that in the pioneer work of early nineteenth century hygienists the universities had no direct share. Revelations at inquiries into the condition of the people, the fear of cholera, and perhaps the publications of the Registrar-General, excited the interest of educated men. The citizens of Liverpool appealed to Huxley for advice, and through his recommendation obtained a classical report by Burdon-Sanderson and Parkes—two great names in the history of preventive medicine. Sufficient interest had been excited by the beginning of the seventies of the last century to secure the establishment in several universities of diplomas in State medicine. The first to move was the University of Dublin, although certain aspects of preventive medicine had been dealt with in the Scottish universities many years earlier. Professor Hope described the later developments of university teaching, and emphasized the importance of universities, not only for the training of undergraduate and graduate students, but as centres to which all members of the community could look for guidance and special instruction. The paper was discussed by Sir George Buchanan, Sir William Macpherson, Dr. Major Greenwood, Dr. G. C. Trotter, and the chairman.

THE NEEDS OF MEDICAL MISSIONS.

NEARLY three thousand delegates, representing every home diocese of the Church of England and many dioceses overseas, headed in most cases by their bishops, assembled at Westminster last week at the summons of the Missionary Council of the Church Assembly, to consider foreign missionary policy. The conference, which was inaugurated by the Archbishop of York and presided over by the Bishop of Salisbury, considered reports on the situation in Africa, India, the Far East, and elsewhere. Resolutions were adopted pledging those present to a great move forward to meet the opportunities arising from the new political consciousness and the new educational and social demands now manifest in many lands. Efforts are to be made in each diocese with the object of making an additional annual provision of £250,000 for missions, for sending out 600 recruits, and for maintaining the level of the replenished missionary staff by engaging 180 recruits a year. An increased supply of men and women for medical missions is considered to be an urgent necessity. Fifteen additional doctors and fifteen nurses are asked for by the Church of England in China alone. It was stated that if the medical profession in Greater London were reduced to the same proportion of doctors to the population as the four hundred million Chinese, London and its suburbs would be left with fifteen doctors only. The contribution of the Church of England to China at present is thirty doctors, distributed over five or six medical schools and twenty hospitals. The report from India stated that in only two dioceses in India do the two chief missionary societies of the Church of England carry out any considerable medical work, and it was urged that fifty more men and women doctors in the missionary centres of India would be of great assistance. In East Africa ten more doctors

¹ Metropolitan Asylums Board. Report on "Rheumatic Infection in Children." By W. T. Gordon Pugh, M.D., B.S., Chief Medical Officer, Children's and Surgical Tuberculosis Services.

² BRITISH MEDICAL JOURNAL, October 31st, 1925, p. 751.

and sixteen nurses are wanted immediately to meet the situation. One of the largest of the African dioceses, Mombasa, needs a doctor to reopen a medical mission which has been closed for want of staff. In West Africa the diocese of Accra, occupying the British territory of the Gold Coast and the mandated territories beyond it, does no Anglican medical work at present, but its bishop is anxious to start a medical mission. In Nigeria there is one Anglican mission hospital, continually overcrowded with patients, but no doctor, the senior sister undertaking minor operations. The Bishop of Lagos is anxious to establish a central mission hospital with a leper settlement. West Africa in all needs at once five more doctors and six nurses. Before the conference closed an earnest appeal was made to young men at the universities. It was urged that a missionary career meant to a young medical man or woman, not a waste of professional education, but, on the contrary, an enlargement and variation of clinical experience, and the opportunity of training or beginning to train a medical school among a new people. In this connexion we may refer to a letter that has reached us from the Shantung Christian University, Tsinan, North China, stating that its hospital is in need of a young radiologist who would be prepared to go out upon a missionary footing. An excellent equipment has been got together, provided largely by the Wesleyan Methodist Missionary Society, one of the co-operating bodies in the university. Particulars of the terms of service may be had from Dr. Fletcher Moorshead, 22, Farnival Street, E.C.4.

SURGICAL SECTION AT THE NOTTINGHAM ANNUAL MEETING.

WE publish in the SUPPLEMENT for this week the provisional programme and the list of sectional officers for the ninety-fourth Annual Meeting of the British Medical Association to be held at Nottingham in the latter part of July. The scientific Sections this year number thirteen, and of these five will meet on all three days—Wednesday, Thursday, and Friday, July 21st, 22nd, and 23rd. At a meeting of the officers of the Section of Surgery held last week to discuss arrangements for the Annual Meeting the following suggestions were made. On the first day it is proposed that discussions shall be held on the surgery of brain tumours and on infections of the urinary tract; on the second day a discussion on carcinoma of the tongue, followed by short communications; and on the third day a combined meeting of the Anaesthetic and Surgical Sections to discuss abdominal anaesthesia, followed by a discussion, confined to the Surgical Section, on the merits of gastro-jejunostomy in the treatment of the affections of the stomach and duodenum. While certain arrangements are already being made for the opening of the five discussions, surgeons interested in any of these matters who would be willing to take part are invited to communicate with the honorary secretaries (Mr. W. F. Neil, F.R.C.S., 9, College Street, Nottingham, and Professor C. A. Pannett, F.R.C.S., 10, Marlborough Place, St. John's Wood, London, N.W.8) before the plans for the work of the Section are completed. In asking us to make this known the secretaries add that there may also be room for a few short communications from members of the Association.

WE understand that the Ministry of Health is about to appoint a committee to examine various questions in connexion with small-pox, alastrim, and vaccinia. A conference on the same subject, arranged by the Health Committee of the League of Nations, was held at the Hague early last month, when a number of conclusions were formulated concerning methods for continuing and intensifying research work into these subjects. The British committee now to be appointed will keep in communication with foreign observers.

Nota et Vetera.

THE MEMOIRS OF SIR WILLIAM HARDMAN.

SOME amusing sidelights are thrown on the hygienic habits and beliefs of an older generation in the second volume of *The Letters and Memoirs of Sir William Hardman, M.A. (Cantab.), F.R.G.S.*, now published by Cecil Palmer. The editor and annotator, Mr. Stewart M. Ellis, biographer of George Meredith, is an authority on the social and literary history of the nineteenth century, and his notes are as admirable as Hardman's high-spirited text. A young Georgian critic has lately referred to the present as "this startling and exciting time and age," but, like Mr. Cardan in Aldous Huxley's novel, many of us, who can remember in their undergraduate or student days the tail-end of a less ascetic epoch, will heave a sigh as they view the photographs of the plump, somewhat self-indulgent Hardman generation, and read of their profuse and well-wined entertainments.

"I had a very select dinner-party at the Club last night," writes Mr. Hardman in 1861 (vol. i). "Meredith, Dante Rossetti, and Dr. Liveing were my party, and I flatter myself they never sat down to a better selected meal in their lives. They were enthusiastic." The menu, given in full, comprised bearded oysters with brown bread and butter, salmon cutlets, fillets of beef *au beurre d'anchois*, lamb cutlets and *fricassée* of chicken with rich sauces, *choux-fleurs au gratin*, macaroni ditto, strawberry omelette, with chablis, amontillado, sparkling hock, chambertin, dry curaçao, and cigars *ad libitum*. "Not very wonderful," says the present, trying to put a good face on the matter, but it was exceptional, as the diarist himself admits. However, the menu of a dinner-party in his own house, one of two successive banquets in 1863, is even more succulent, and, says his editor, may be taken as typical of one of the dinner-parties of the period. Ten years earlier, by the by, the Hunterian banquet at the Royal College of Surgeons offered its guests a choice of eighty dishes!

The rich dieting of that past age claimed its victims, and early in 1864 we find the diarist writing: "I have been woefully seedy for some weeks. . . . I believe now that I have had a very narrow escape of typhoid fever," a disease presumably then attributed to excess. "My digestion has been very shaky for months, and at last the lining membrane of the stomach became utterly deranged, and of course liver and kidneys chimed in." Dr. Robert Liveing, the fellow feaster, who in his time succeeded to Sir Erasmus Wilson's practice, prescribed sulphuric acid, as though for diarrhoea, to be taken twice daily, and, says Hardman, "this diluted sulphuric acid has had an effect little short of magical on my whole system. I am a changed man." Thus he refers naively to a stock remedy for a common case.

Sir William Hardman died at the age of 62 in 1890. He was latterly a public man, a knight and member of Parliament, and recorder of Kingston in Surrey, as well as editor of the *Morning Post*. Many of his brilliant literary friends had died in early middle life, as Mr. Stewart Ellis has pointed out in his volume of essays *Mainly Victorian*, where the last phases and deaths are often shown to be due to unwise living, late hours, overfeeding, and alcohol in excess. It may be that Hardman's long and mostly unpaid labours kept him in health in a jovial epoch.

It is curious, however, that as a public man he seems to have been so unaware of the health activities of his time and day. Typhoid, we have noted, he attributes by implication to a disordered state of the digestive organs. To him it is not the well known endemic "London fever," due to polluted water, which raged till well on in the seventies of the past century. Of cholera he has nothing to say. Anaesthesia is known, but not antiseptics, much less asepsis. The work of the Board of Health is probably unheard of by him, for he mentions John Simon, "that well-known medico," as "the man who in some way or other seems to be responsible to Government for the health of Britishers." Simon, by the by, had not been very

well, and, "on the principle of 'physician, heal thyself,' " had resolved to spend two months in Greece, Turkey, and Egypt. The trip was to have been undertaken in the society of Thomas Woodbine Hinchliff, of 64, Lincoln's Inn Fields, author of *Over the Sea and Far Away*, and one of the founders of the Alpine Club. In his privately printed autobiography Sir John Simon mentions neither the trip, nor Hinchliff, nor William Hardman, though he was much in their circle, and was a friend of Rossetti, Thackeray, and the rest of that brilliant genial generation. That Simon knew Greece well is certain, for to the present writer in the eighties he spoke more than once of the grey Athenian sky and the beauty of Greece.

It was John Simon who, in the sixties, prophesied that in fifty years' time vaccination would be universal or quite a thing of the past. The prophecy had been fulfilled neither way when, in about 1912, the fifty years had run their course. In his earlier days the educated classes were almost fanatical vaccinists. Hardman describes a small-pox scare, when "everybody" was vaccinated over again. While the medical attendant of his family was vaccinating Hardman, the latter was rash enough to express sympathy with the views of Bishop Colenso, of Natal, on the Pentateuch. "A nervously vindictive extra prod or two of the vaccinating instrument" thereupon reminded him that his doctor was an Irvingite Saint, and that he trod on dangerous ground, and should in future find out the tenets of his surgeon before undergoing an operation. Mrs. Hardman attributed her earache to vaccination, and the "Colenso" pustule on his arm gave the diarist much trouble. At this time (May, 1863) the surgeon-major of the Royal Horse Guards (Blue) wrote to the *Times* recommending the use of *Sarracenia purpurea*, or pitcher plant, as an invaluable remedy. Mr. Logie had cured four cases of confluent small-pox with an infusion of this plant, which "seemed to arrest the development of the pustules, killing, as it were, the virus from within, thereby changing the character of the disease and doing away with the cause of pitting." The diarist is of opinion that this is decidedly worth making a note of. He had heard a vague rumour that the Indians used some root as a specific in small-pox, but had not so far comprehended the matter.

V. G. P.

Scotland.

CRICHTON ROYAL INSTITUTION, DUMFRIES.

THE eighty-sixth annual report of the Crichton Royal Institution, Dumfries, dealing with the year 1925, has just been issued. The number of patients treated in the institution during the year was 1,265. The numbers actually on the register at the close of the year were 450 males and 516 females, and of these 621 were private patients and 345 parochial patients. Among the private patients 216, or more than one-third of the total, were voluntary boarders who might obtain their discharge on giving three days' notice to the superintendent. During the year a good deal of work has been done for the extension of the institution, especially by the construction of a hall for the accommodation of the female staff, which, it is expected, will be completed at an early date, and of a new hospital wing, which makes provision for 100 extra beds, being divided into four units of twenty-five beds each. This wing is situated on rising ground, with a fine view south-westwards over the Nith valley to the Galloway hills, and in accordance with the most modern ideas of construction of mental hospitals it is only one story high. In the report by Dr. C. C. Easterbrook, physician-superintendent of the institution, it is pointed out that 212 voluntary patients were in residence at the beginning of the year and 216 on December 31st, while, during the year, 150 had been admitted, 126 had left, and 20 had died. The total of 362 voluntary patients under treatment during the year is the highest hitherto recorded. Of those admitted, 32 had already had mental hospital treatment and 118 had not previously been in a mental hospital. The voluntary patients had suffered

from the same kind of mental illness as the certificated patients, but mostly in lesser degree or in earlier stages, the patients having more insight into their condition and recognizing the need for mental hospital treatment. Among the certificated admissions, numbering 120, the majority were certified for the first time, although 24 (12 men and 12 women) had had one or more previous attacks of certified insanity, from which they had recovered. The mean age at admission was 45.4 years, the oldest being a woman of 86 and the youngest a boy of 13. Fully half were in the middle period of life, nearly a quarter below 30, and nearly a quarter above 60. There were 62 single persons, 48 married, and 10 widowed. The occupation of the patients had been of a professional nature in 12 cases, commercial in 11, industrial in 16, agricultural in 24, and domestic in 48; 9 were unemployed. With regard to the causes of insanity, apart from the usual predisposition of a nervous constitution, impairment of bodily health had been noticed in almost all the cases admitted. The stress which had precipitated the psychosis had been most frequently noted as general debility and exhaustion, anaemia, arterio-sclerosis and heart disease, catarrhal states of the respiratory or alimentary tract, especially as a sequel of influenza (10 per cent.). Biological stresses were also noted as of great importance, comprising the climacteric in 20 per cent., senility in 19 per cent., puberty and adolescence in 19 per cent., while 8 per cent. of the female cases began after the stresses connected with child-bearing. The forms of mental illness included melancholia (31 cases), confusional delirious insanity (26 cases), delusional insanity (18 cases), mania (12 cases), dementia (11 cases), epileptic insanity (11 cases), amentia (6 cases), dipsomania (3 cases), phobia (1 case), and general parietic insanity (1 case). Of the cases discharged during the year, which numbered 218 (105 male and 113 female), 126 had been voluntary admissions and 92 had been certificated. Of the voluntary patients admitted 61 left recovered, 58 improved, and 7 unimproved, the recovery rate being 40.6 per cent. of the number admitted. Of the certificated cases 54 recovered, 34 improved, and 4 unimproved, the recovery rate being 35.5 per cent. of the number admitted. The forms of mental illness in which recovery was principally achieved were confusional insanity, delusional insanity, mania, and melancholia, and as regards the time elapsing between onset and recovery in these cases, this had been less than six months in 52 per cent., from one-half to two years in 35 per cent., and more than two years in 13 per cent.; 81 patients had died during 1925, of whom 61 were certificated and 20 voluntary. Based on the average daily numbers, the death rate had been 8.3 per cent. The causes of death had been chiefly senility, exhaustion from mental disease, fatty and valvular heart disease, pneumonia, pulmonary tuberculosis, cerebral apoplexy, and epilepsy. The mean age at death had been 59.2 years.

Reference is made to various improvements and extensions made in the buildings and in the grounds of the institution, and to various agricultural operations which have been carried out under the auspices of the West of Scotland Agricultural College. It is mentioned that, in accordance with an arrangement now in force, the annual rate of board for rate-aided patients has been fixed at £48 6s. 5d. a head. During the year the sum of £1,195 had been expended in grants from the Crichton Charitable Fund in reduction of cost of board, and 54 patients had participated in the benefit thereby afforded.

GLASGOW SCHEME FOR PAYING HOSPITALS.

At a meeting of the Southern Medical Society of Glasgow, at the Victoria Hospital on January 21st, Mr. A. E. Maylard, F.R.C.S., delivered an address upon the relation of hospitals to the public and the profession. In recent years the large public hospitals and infirmaries had, he said, become most efficiently equipped, so much so that it was practically impossible for treatment of a character equal to that existing in the modern hospital to be obtained elsewhere. The private nursing home did not supply many of the needs of modern medicine and surgery. Two remedies were possible: one was to build hospitals for paying patients with an equipment equivalent to that of

the existing large hospitals, and the other to admit all classes of the community, both those who paid and those who did not, to the general hospitals and their annexes. Mr. Maylard believed that the latter presented the greater advantages, for the admission of paying patients to the general hospitals would benefit both classes by reason of the economy that could be effected. All patients would benefit from the various special departments, such as electric and light installations, and laboratories for biochemical, bacteriological, and pathological investigations. The increased pressure on beds could be met by the erection of auxiliary hospitals in outlying districts, where plenty of ground was available; they would consist of bungalow pavilions, and would receive convalescents from the hospitals in the city, whose treatment could be more advantageously carried out in the country, as had been already found in the case of children. Another means of relieving the additional pressure on the city institutions would be to encourage the erection of cottage hospitals in country towns. The advantages which would accrue to the public in carrying out these proposals would equally affect the medical profession.

In the large infirmaries of Scotland a step has already been taken in the direction suggested by Mr. Maylard. As mentioned on January 23rd (p. 164), a piece of ground has been presented by Mr. J. Macfarlane, LL.D., and Mr. G. W. Macfarlane to the Glasgow Royal Infirmary, for the erection of an auxiliary hospital at Canniesburn, and it is expected that a large sum of money will be shortly forthcoming for proceeding at once with the erection of the contemplated hospital. This will greatly relieve the pressure on the Glasgow Royal Infirmary. On January 30th (p. 218) mention was made of an initial step taken by the Victoria Infirmary of Glasgow in acquiring ground at Thorntonhall for an auxiliary hospital. The Edinburgh Royal Infirmary, as the result of a benefaction which has accumulated from a date some years before the war, has acquired several contiguous mansion-houses, situated on ground on the south side of the city. Part of this Astley-Ainslie Institute, sufficient to accommodate over fifty patients, is already in occupation, and it is expected that the administrative buildings and main portion of this auxiliary hospital will be completed in the course of the present year.

The question whether the general hospitals can be made available for all classes of the community by the establishment of paying wards is one which, although the practice has been in operation for years in the United States, has not yet been fully considered in this country.

The question of construction to which Mr. Maylard adverted is also discussed by Sir George Beatson, as mentioned at page 254. The one-story bungalow or pavilion hospital was generally adopted in the large hospitals of Germany prior to the war. In the case of the Rudolf Virchow Krankenhaus, which was completed in 1914 for 1,000 beds, the hospital was so laid out that the number of pavilions could be immediately duplicated on the outbreak of hostilities without any increase in the administrative buildings or general services, such as water supply, heating, and electricity. This conducted both to rapid extension and to economy.

Ireland.

MEDICAL REGISTRATION IN THE FREE STATE.

The Minister for Local Government, moving the second reading of the Medical Bill, 1926, said that its object was to continue in operation until August 21st next the Medical Act of 1925. The Free State Government had been under the impression that the existing arrangement under the Medical Acts would have been continued in force by the combined operation of the Constitution and of the Adaptation of Enactments Act, but a position arose on the other side which made it clear that the continuation of the *status quo* could not be counted upon in Ireland after the signing of the treaty. Accordingly, if the rights of the students qualifying in Ireland were not to be seriously jeopardized, it was necessary to introduce temporary legis-

lation providing for the *status quo* while the question was under review. Negotiations were going on between the parties interested—the medical profession, the medical schools, the General Medical Council, and the two Governments concerned. While he was not in a position to say that the matter had been finally settled, he would not be unduly optimistic in stating that a line had now been hit upon which would probably preserve the existing rights of students qualifying in the Irish Free State, without in any way derogating from the status of the Free State under the treaty. It was, he said, necessary, if the whole position of the medical profession in the Free State was not to return to chaos, that the Act should be continued. Sir James Craig, supporting the second reading, said that the medical profession was extremely anxious that a permanent bill should be brought in as early as possible, so as to do away with the uncertainty that existed and was depleting the medical schools. A certain amount of anxiety existed in the minds of students in their final year lest anything should be done to prevent the bill from being passed in time to enable them to get registered. He urged the Minister to endeavour to get the bill through at the earliest possible moment. The second reading was passed. It was arranged that the Committee stage should be taken on Wednesday, February 3rd, and that the Minister should move the suspension of standing orders to allow the remaining stages to be taken. It is expected that this will happen, but the result was not known officially when we went to press.

COMMITTEE ON WORKMEN'S COMPENSATION.

Dr. T. Hennessy, Irish Medical Secretary, giving evidence before the Departmental Committee on Workmen's Compensation in the Irish Free State, said that adequate treatment of minor injuries was essential in order that an injured person might be able to return to his employment. Many injuries, he said, were inadequately treated owing to the want of facilities in every district. A medical practitioner of ordinary skill could not be considered to have the necessary knowledge to treat certain injuries by massage and electricity. Where a certain recommended treatment was not accepted by a patient the matter should be referred to a medical referee, whose decision should be final. If the injured person unreasonably refused to undergo such treatment the compensation should be reduced. Witness advocated training for workmen permanently disabled. Use might be made of institutions set up by the Ministry of Pensions. No attempt should be made to dispense with the patient's own doctor. Disputes due to conflicting medical evidence should not be heard in open court, but should be submitted to a State medical referee, with a right of appeal to a board of medical referees. The State medical referee should have the supervision and control of all first-aid appliances and arrangements, and he should be available for consultation if required by the injured person's doctor. He should also have power to enforce treatment after consultation with the injured person's own doctor, and reduce benefit if treatment was refused. A medical assessor would not be necessary if this procedure were adopted, but should the present arrangements hold, whereby disputed cases were heard in open court, then the medical assessor should be summoned in all cases where medical evidence was to be taken. The judge should not have the option of saying whether or not the medical assessor should be present. Regarding the possibility of establishing a percentage scale of incapacity, the witness said that the difficulties were very great, but the adoption of such a scheme might be possible in such specific instances as the loss of an eye or total or partial loss of a limb. The experience of the Ministry of Pensions might be useful. He thought the best plan would be to postpone such a scheme for a time, because, were treatment and training obligatory, there would later on be more satisfactory data. He advocated payment of compensation from the fourth day, because the injured workman who was tempted to make the most of his condition in order to come within the fourteen days' rule would probably resume work much sooner. To pay compensation from the first day would be impracticable in view of the many trivial cases which lasted for one or two days. Payment of

compensation, no matter when commenced, should not be held as an admission of liability. At a subsequent session of the Departmental Committee Dr. Pugin Meldon, certifying surgeon for Dublin City, in giving evidence, suggested that there should be a probationary period for the medical examination of persons between the ages of 14 and 16, as it often happened that poor children who were badly housed and fed showed much improvement after being at work for some time. He inspected factories and examined all young people between 14 and 16. His duty was to satisfy himself that they were suitable for the work they were doing and the work they would have to do later on. At present he had no power to re-examine them. In his examination he had to consider that the work was suitable, and that they were not likely to be a source of danger or infection to other workers. Previously he had to examine in the case of all accidents, but now he only examined cases notified to him by the inspector of factories, and these were confined to poisoning cases. He suggested that the Act should be extended to any injury or disease, and not a particular disease specific to a particular employment. All big factories had now first-aid squads amongst their workers, and he thought that every factory, no matter how small, should have a first-aid case, and that some of the workers should be taught the principles of first aid. Injured workers should be notified of the time and place at which to present themselves for examination. At present they came without notice at very inconvenient times.

England and Wales.

LIVERPOOL SCHOOL OF TROPICAL MEDICINE.

ON the eve of his departure for a tour in West Africa the Hon. W. G. A. Ormsby-Gore, Under Secretary for the Colonies, was entertained at luncheon, on January 20th, at the Exchange Station Hotel, Liverpool, by the Liverpool School of Tropical Medicine; Mr. J. A. Tinne, M.P., presided in the absence of Sir Francis Danson, chairman of the school. In the course of a speech Mr. Ormsby-Gore expressed the high admiration felt at the Colonial Office for the work done at the Liverpool School of Tropical Medicine, and said he would do everything in his power to further the importance and value of research. The health of West Africa had, he said, immensely improved by the aid of science and by the self-sacrificing zeal of men who had gone out there, but there was still plenty of room for men like Sir Alfred Jones. He congratulated the school and Professor Newstead on the research work carried out in connexion with the ravages of sleeping sickness. Some of the finest and most profitable areas had been depopulated and thrown out of agricultural production by the tsetse fly, while Uganda had lost at least one-tenth of its population in one year by its ravages. The foundations of success in the expansion of British trade and commerce with the tropics was, he said, linked up with the two fundamentals of health and agriculture.

THE NURSING SERVICE AND MENTAL HOSPITALS.

The Board of Control, after consideration of the report of the Departmental Committee on Nursing, together with the report of the conference of mental hospital authorities last April (*JOURNAL*, 1925, vol. i, pp. 807 and 854), has issued a circular letter (No. 677) to the medical superintendents and the visiting committees of each county and borough mental hospital in England and Wales. The following steps are suggested to improve the status of the mental nursing service. The nursing staffs should be graded on a uniform system, and the senior nursing posts be held by individuals who are certificated or registered in both general and mental nursing. The rank of senior probationer should be limited to those who have passed the preliminary examination. The Board considers it essential that in any case either the matron or assistant matron, the sister tutor, and the sister in charge of sick wards should be doubly trained. Encouragement should be given to members of the existing staffs who are certificated or registered in mental nursing only to com-

plete their training in general nursing, and so to qualify for the more important posts. This, it is suggested, could best be done by an arrangement with some general hospital, preferably within the area served by the mental hospital, and recognized as a training school. Entrants to the mental hospital nursing service who have undergone a full general hospital training previously should receive a higher initial salary than those who have not. It is recognized that the holders of the higher posts, and especially those for which double training is necessary, should be adequately remunerated, and the Board hopes that these posts will come to be regarded as prizes in the profession of nursing. Wherever possible separate nurses' homes or hostels should be provided at some distance from the patients' quarters, with reading rooms and adequate arrangements for indoor and outdoor recreations.

THE "BIRMINGHAM MEDICAL REVIEW."

The *Birmingham Medical Review*, which ceased publication in 1919, has now reappeared as the organ of the Birmingham Medical Institute; with it has been amalgamated the *Midland Medical Journal*, in which the reports of the Panel Committee meetings have appeared. It is hoped that the new journal will play an important part in bringing together the university medical school, the hospitals, medical societies, and those engaged in medical practice in the city and surrounding country. The editor is Dr. K. D. Wilkinson, assistant physician to the Birmingham General Hospital. The first number—January, 1926—contains the first of the two Ingleby lectures on auricular fibrillation, delivered by Dr. J. G. Emanuel in Birmingham last May, and a very interesting memoir by Dr. W. H. Wynn of Dr. William Withering, who practised in Staffordshire and Birmingham in the eighteenth century, and is renowned for the introduction of digitalis into medical treatment. Dr. A. V. Bernays contributes some amusing meditations of a general practitioner, and Mr. G. P. Mills describes the treatment of acute perforative peritonitis. The proceedings of the Midland Medical Society and reviews of books are also included. The journal is published by Cornish Bros., Ltd., 39, New Street, Birmingham. The annual subscription to members of the institute is 7s. 6d., and to non-members 13s. 6d., post free; single copies may be obtained for 1s. 6d. net.

Correspondence.

THE CONSTITUTION AND PRACTICE OF THE GENERAL MEDICAL COUNCIL.

SIR,—There is a widespread feeling that the General Medical Council requires a good deal of overhauling in the interests both of the medical profession and of the British public. It seems to some extent to have lost touch with the medical profession, and has somewhat shaken the confidence of the lay public. When anyone finds fault with the General Medical Council the reply which it all but invariably gives is that it is a body conditioned by the Privy Council. Are we to infer that it is a quantity so absolutely negligible that H.M. Privy Council will pay no attention to anything it may have to say? In the meantime it sits as a court of justice and dispenses its sentences. That many of the persons so sentenced deserve their fate goes without saying, but that is no reason why the accused should not have a right of appeal. Moreover, the present system tells specially hardly on poor practitioners in Scotland. They have to fee lawyers in London, and possibly even go to the expense of taking a number of witnesses from Scotland to London and keeping them there till the General Medical Council hears the case.

I myself am in a predicament. I wish to read a paper on miner's nystagmus at a meeting which will be attended by colliery managers, probably by colliery proprietors, and by the officials of the Miners' Union. The audience will be almost entirely composed of laymen. I hesitate to make this contribution, although naturally I believe it to be important, for it is within the range of the possible—be it said, I think, improbable, for the communication does not recommend any mode of treatment—that the General

Medical Council might swoop down upon me and declare that a paper read to a lay society was nothing less nor more than a tout for patients, and that my conduct was infamous in a professional sense. A good number of years ago I was, I believe, of considerable use to the mercantile marine (at any rate an association of ships' officers said I was, and expressed their indebtedness) by a publication which was made by me in the *Liverpool Journal of Commerce* on seamen's eyesight. That communication prevented some unnecessarily severe regulations being made by the Board of Trade—regulations which would have thrown a great number of first-rate seamen out of employment. My contribution originally took the form of two papers to the Royal Philosophical Society of Glasgow. I dare not intervene in this way again in an economic problem, because the General Medical Council has it in its option to say that such publications, appearing in lay journals, partake of the nature of an advertisement, and it might forthwith score my name off the *Register*, without my having any right of appeal to any tribunal. It is quite open to it to do so.

So far, briefly, for destructive criticism; I will now venture to say a few words of a constructive nature. I would change the membership of the General Medical Council, and I would change the methods of its election. I would also include on it a certain number of laymen, and I would alter entirely its present penal system. To take the last point first. The court before which an accused person is tried consists of all the members of the General Medical Council, about forty in number, none of whom are trained lawyers. The charge is framed by the solicitor to the General Medical Council. Certain points of law are referred by the General Medical Council to an assessor, and the accused man may or may not have, according to the depth of his purse, the assistance of a legal representative. He may or may not be able financially to bring witnesses from all over the country, and he may have to stay an indefinite time in London. I would alter the procedure to something like what takes place in maritime cases. When a ship's officer has had an accident of a serious nature the Board of Trade may consider it necessary to have an investigation. I suppose the underwriters of the ship may also think that necessary. If a maritime case occurs in England it is sent to the Admiralty Court, and it is then heard by a judge, who has associated with him two of the elder brethren of Trinity House. In Scotland maritime cases are heard by a judge, and he also has associated with him two nautical assessors. Now I think something similar might be introduced for these medical cases. Why should they not come before a judge, with two senior medical practitioners associated with him as assessors? If there were regular courts, such as exist for marine investigations, the penal work of the General Medical Council would become much better defined. In all innocence I may publish a statement, say, at a meeting of the Royal Philosophical Society of Glasgow on some physiological subject, and I may thereafter find myself judged guilty of infamous conduct. Another man may have a very close connexion with an advertising optician, who brings the man before the public and thereby helps to fill his consulting rooms, and yet the General Medical Council may not feel it incumbent upon it to take any action.

There is also one other great objection to the present arrangement, and it is that men of first-rate standing in the profession are not likely to leave their laboratories or important clinical work in hospitals, or important work as teachers, to spend time in London for penal cases. No doubt some very good men might be obtained from London itself, and perhaps from that district generally called the Home Counties. Men of that stamp might find it possible to give a few hours during the days that it was necessary to be in attendance at the General Medical Council, but no man actively and permanently engaged, either as a physician or as a surgeon, working in his laboratory, as also in his wards, is likely to join the General Medical Council and give up his work for an indefinite time.

Now as regards the composition of the General Medical Council a good deal must be said. I favour the introduction of a lay element. I also favour an age limit. Nobody should be a member of the General Medical Council after

the age of 65. Practitioners, after a certain time of life, although excellent in many ways, are apt to lose touch with the more recent developments in surgery and medicine. I think nothing can better show the advisability of a retiring age limit than the present condition of the General Medical Council. There are very few of the younger and hard-working investigators in its membership. Further, I should allow no man to sit for more than five or six years continuously on the General Medical Council. After that he should retire. I am aware that some practitioners are of opinion that, having served five years, a member should not be eligible again, but that, I think, would be a mistake. The five years' membership with a time of retirement would allow an unsuitable man to be permanently shelved, but would also keep the door open for a good man to return. But it is entirely wrong to have a body of elderly men, in some cases old men, sitting on indefinitely.

Probably the most important part of the work of the Council is to regulate the medical curriculum. The final cause of medical education is to produce well trained and capable practitioners, and with that object I would alter entirely the composition of the Council and give greater prominence to the clinicians. There are certain sciences which a medical student must study before he begins medical work. Amongst these are anatomy, biochemistry, biology, and physiology. I would have an anatomist elected to the General Medical Council by the votes of all teachers of anatomy whose courses of instruction are recognized for medical degrees in the British universities or by the other bodies whose diplomas qualify for registration. On the same principle I would have a biochemist, a biologist, and a physiologist elected. Perhaps in each case two would be required—namely, one elected by anatomists, biologists, biochemists, and physiologists in England, and the other by the same class of constituents in Scotland, Ireland, and Wales.

In the same way I would have three physicians appointed by the teachers of systematic and clinical medicine, at least one of them being elected by the physicians in Scotland, Ireland, and Wales. I would add three surgeons similarly elected, and three obstetricians. There should be at least three pathologists and three bacteriologists. There should be a representative of each of the more important specialties—for example, eye, throat and nose, ear, and insanity. There should be added a good representation of public health officers and a certain number elected by the general practitioners. The Crown representatives might continue as at present and be nominated by the Ministry of Health. Possibly these should always be laymen.

That ought to give a sound board for medical education. When penal cases occurred they should be referred to the tribunals already indicated, and the finding of the tribunals would be reported to the General Medical Council, who would remove or retain the name of anyone accused according to the finding of the tribunal.

The present system is cumbersome, and is particularly hard on registered practitioners who are at a distance from London. The General Medical Council would, of course, continue to sit in London.—I am, etc.,

Glasgow, Jan. 26th.

FREELAND FERGUS.

THE ULTRAMICROSCOPE IN CANCER RESEARCH.

SIR,—There are points of principle raised in the letter you published in your issue of January 16th (p. 119) from Sir G. T. Beatson, to which some reply may be of interest to your readers. There are other controversial points raised which are not within my province, and which, therefore, I pass over.

The title chosen by your correspondent is itself unfortunate, as it indicates some confusion of ideas. The ultramicroscope has not been used by Gye or by me in any of the work we have done, nor does it appear likely that it ever will be so used. The term is only applicable to an apparatus for rendering visible small particles that are beyond the resolution limits of any microscope objective, used with ordinary light. A dark-ground illuminator often makes objects visible that are ultramicroscopic; but that

is not its purpose; it is intended for the observation of bodies that are, at least in one dimension, resolvable by the observational system used. Whether a body is made visible or not depends mainly on the intensity of the light used, and an ultramicroscope is designed to do this regardless of the resolution that is obtainable.

Whether the range of filterable viruses is as extensive as your correspondent suggests is questionable. There are physical reasons for suggesting that there are none so small as to be beyond the power of a microscope illuminated with ultra-violet light of wave-length 200 μ , but this point it is impossible to follow within the limits of a letter. This method has been used in the publication already made by me, and the wave-lengths used are indicated in each case. The use of short ultra-violet rays is rendered difficult by the relative opacity of the culture or other medium in which the organisms are suspended, and this is the point on which further research is now proceeding. No suggestion has been made by me that x rays have been used in any way in this work. It is quite true that experiments are in progress in which such rays are being used, but their utilization for microscopical work is still far off, and may not be achieved within reasonable time. The references to such work by your correspondent are entirely misleading, and are due, I imagine, to careless reading of my published results. The same cause may be assigned to the reference to the work of Professor Baly of Liverpool on photo-synthesis. I am fully conscious of the possible changes that may occur to living bodies (and, of course, under certain conditions to non-living ones) as the result of using ultra-violet light in microscopy, and have drawn particular attention to this aspect of the work. It was this very point that made it necessary to provide apparatus in which the exposure was reduced to a minimum, and all the preliminary work was done in visible light to ensure that no changes were set up due to the radiations used. It was further stated that considerable time had been spent in the study of the changes occurring in bacteria as the result of exposure to ultra-violet light, and that publication of the results would be made later. It follows, therefore, that not only were such possible changes provided against, but that sufficient knowledge of such changes had been acquired to enable them to be recognized if, after all, they should take place. The concluding reference to Professor Bechhold's work again suggests that his paper has not been carefully read. In any case the purpose of his experiments is different from mine, so that the reference is irrelevant.—I am, etc.,

National Institute for Medical Research,
Hampstead, N.W.3, Jan. 27th.

J. E. BARNARD.

NOVASUROL AND OTHER DIURETICS IN CARDIAC OEDEMA.

SIR,—Like Dr. Howarth (January 30th, p. 186), I was much interested in Dr. C. G. Lambie's article in the *JOURNAL* of January 16th (p. 80) on the diuretic action of novasurol, as I have been making use of this substance largely during the past six months in cases of cardiac oedema and of ascites. If the drug is likely to come into general use, however, it is, I think, important to emphasize a point that Dr. Howarth refers to—namely, that profuse watery diarrhoea is very likely to follow its administration. I notice that Drs. Lambie and Haworth have both employed 0.5 c.cm. as the initial dose, while the proprietors (the Bayer Company) state that the diuretic dose is 1 to 2 c.cm. There is not the least doubt that 1 c.cm. as an initial dose is extremely inadvisable. In some cases in which I have administered this dose, after seeing Keith's work at Rochester, I found that the resultant diarrhoea was so extreme as to produce serious collapse. I therefore think it well to sound this note of warning, and to urge that the dose mentioned by Drs. Lambie and Howarth should never be exceeded till its effect on the individual patient has been determined. In children proportionally small doses should, of course, be employed.

I can confirm from my own experience everything that has already been stated regarding the diuretic action of this remedy.—I am, etc.,

Dublin, Jan. 30th.

T. GILLMAN MOORHEAD.

SPENCER'S "CAESAREAN SECTION."

SIR,—I am glad that the reviewer of my book has corrected those startling comparative figures which he gave. I also should like to make a correction. The "5.5 per thousand" on page 13 of my book should be "5.6 per thousand," being the equivalent of the "32 in 5,647" on the opposite page 12, where it is definitely stated that the figures refer to Caesarean section for contracted pelvis only. It would have been better to give the frequency for all indications, which was 6.5 per thousand—37 cases (with one maternal death) in 5,647 labours.

In stating that the cases were delivered "in the maternity" (the 'in' is not italicized in my book), I, of course, meant the whole maternity department, both indoor and outdoor; the same in the case of the Rotunda Hospital. In no other way can the frequency of the performance of Caesarean section by the staff of a hospital be ascertained than by including the outdoor maternity department, from which the indoor cases are largely derived.

The frequency at University College Hospital during the three years was: for contracted pelvis 5.6 per thousand labours, for all indications 6.5 per thousand labours; the frequency at the Rotunda Hospital for all indications during one year was 5.1 per thousand. Your reviewer must, I think, admit that there is a great difference between the frequency represented by these figures and by 88 per thousand. I take this opportunity of thanking him for his careful review of my book, and especially for his generous acknowledgement that he has profited by the teaching it contains.—I am, etc.,

London, W., Jan. 31st.

HERBERT R. SPENCER.

THE NEW OUTLOOK ON CANCER.

SIR,—In his instructive British Medical Association lecture, published in the *JOURNAL* of January 30th (p. 175), Dr. Cramer discusses the production of immunity to cancer by a previous malignant growth.

He adds, "It would be interesting to follow the history of patients who have been operated on successfully for, say, a carcinoma of the tongue or of the breast, so as to find out whether they have developed subsequently a cancer in some other organ." Some of them certainly do so. Last year I had under my care two such patients. Their histories are as follows: One had had both breasts removed for carcinoma with an interval of several years between the operations. Ten years after the last operation I saw her with a large carcinoma of the rectum, from which she died a few months later. The other had had a Wertheim's operation performed eight years previously by the late Dr. Walter Swayne, for carcinoma of the cervix. She came to me with a primary carcinoma of the rectum, which I removed by an abdomino-perineal resection.

I suppose that most of us have occasionally seen individuals suffering from carcinoma in more than one organ at the same time. I can recall several such cases—for example, breast and lip, carcinoma of stomach and rodent ulcer of face, etc. Such combinations are, however, so rare as to excite comment, in spite of the commonness of single cancers. It is not improbable, therefore, that one growth may produce a relative though not an absolute immunity to the development of carcinoma elsewhere.—I am, etc.,

HUBERT CHITTY, M.S., F.R.C.S.

Clifton, Bristol, Feb. 1st.

THE TERM "SCARLET FEVER."

SIR,—Sydenham has usually been credited with the first use of the term "scarlet fever" by his Latin rendering of it, "febris scarlatina." But Hirsch pointed out that it is probable that he was not the first to use the Latin words (*Handbook of Geographical and Historical Pathology*, vol. i, p. 172, footnote, English translation by Dr. Creighton).

Now, from the manner in which Sydenham writes of scarlet fever, and from the allusion he makes to it in the chapter on measles of the year 1674 (p. 217 in Greenhill's Latin edition), where he compares the peeling that follows certain cases of measles with that of scarlet fever, it seems

to me that he wrote his account of the disease, not because it was new either to himself or to any of his contemporaries, professional or lay, but because it was one of the intercurrent fevers which he had met with during a certain epidemic constitution, and that he was Latinizing a vulgar name.

It does not appear to have been noticed that Samuel Pepys wrote as follows in his diary under the date November 10th, 1664—that is, twelve years before Sydenham published his account: "My little girl Susan is fallen sick of the meazles, we fear, or, at least, of a scarlett feavour" (p. 286, vol. iv, of Wheatley's edition); from which it would appear that in those days the name "scarlett fever" was known to the laity, and that it referred to an indefinite affection which was less severe than measles. Pepys's reference to it bears out Sydenham's statement that scarlett fever was in his time hardly more than the name of a disease. Sibbald, it is true, writes in 1684 of scarlett fever as a disease of recent origin. But Willan, referring in 1808 to Cotton's account of it at St. Albans in 1748, speaks of the name scarlett fever as "an old appellation of a disease certainly not new" (quoted by Creighton, *History of Epidemics in Britain*, vol. ii, p. 698, note).

Can any of your readers tell me whether the name "scarlett fever" has been used by any British writer, lay or professional, before the time of Pepys and Sydenham?—I am, etc.,

London, N.W.3, Jan. 25th.

E. W. GOODALL.

** The earliest reference to the term "scarlett fever" in the *New English Dictionary* is dated "1676—James Cooke, *Marrow Chirurg.* vi, ii (1685), 214."

RECTAL ANAESTHESIA.

SIR,—I should like to add my testimony to the advantages of rectal anaesthesia in operations (*BRITISH MEDICAL JOURNAL*, December 26th, 1925, p. 1223) on the head and neck, or even any part of the body, when a surgeon is working by himself, as in the navy and mercantile marine. That the method is not sufficiently widely known is very evident, because I seldom meet a surgeon who is not delighted to learn the technique whenever one honours me with a visit, and there is practically always a case in hospital as a demonstration of its utility.

The mixture I use is one part olive oil, three parts ether, and the amount given by a catheter high up in an empty rectum is 3 eg. per kilogram of the body weight of the patient, or one fluid ounce per twenty pounds English scale.

The anaesthetic should be given about half an hour before the surgeon is to be ready for the patient and the rectum washed out through an anal speculum after the operation is over. The anaesthesia lasts from four to six hours, with no ill effects, and gives a surgeon working single-handed ample time to supervise every detail, such as boiling instruments and washing his hands without hurry, or anxiety from the anaesthetized patient.—I am, etc.,

H. E. S. STIVEN, M.D.,
Principal Medical Officer, Egyptian
Government Hospital, Port Said,
Egypt.

January 14th.

HAEMOCHROMOGEN TEST FOR BLOOD.

SIR,—I am afraid Dr. Dilling (January 30th, p. 219) has mistaken the object of our article on the above subject. As we stated, the subject was investigated by numerous observers about the same time as Dr. Dilling's book was published. These observers did not consider the haemochromogen crystal test better than the haemin test, and with some undoubted blood stains they failed to obtain a positive result. Dr. Dilling himself states that he failed with blood stains over six months old when using the methods then employed—a striking contrast to the results described by us.

Since this date Takayama has proposed a solution which he and workers in Germany consider a great improvement,

and which for the sake of description we have referred to as Takayama No. 2. We can find no mention of this in the English literature, but previous to this the production of haemochromogen crystals as a test for blood was referred to by Sutherland in 1907 in his well known book on the examination of blood stains.

Our article was intended to draw a comparison between the method advocated by Takayama and the haemin crystal test, as of course the test as previously described had been tried and found wanting. We have no hesitation in saying that we consider the haemochromogen crystal test, performed as we have described, to be better than the haemin test, and I have used it (in addition to the spectroscopic tests, etc.) in preference, in all stains that have been submitted to me for examination recently.

That pyridine alone will produce haemochromogen crystals has been known for a long time (Donagany, 1893). We had noticed that when not using grape sugar crystals were more difficult to obtain, and I think Dr. Dilling's explanation of its action is probably correct.

I shall be very interested to hear Dr. Dilling's results with this method.—I am, etc.,

DOUGLAS KERR.

Edinburgh, Jan. 31st.

OPERATIVE TREATMENT OF ACUTE PERFORATED ULCER OF THE STOMACH AND DUODENUM.

SIR,—In the interesting article by Mr. Arthur Evans in the *JOURNAL* of January 30th (p. 184) kindly reference is made to my critical attitude towards routine performance of gastro-enterostomy at the time of suture of a perforated ulcer. I should like it to be understood, however, that my objection is against the routine adoption of the measure, for I am well aware that when the surroundings and condition of the patient are good and the ulcer is a chronic one situated in the duodenum, or if rather much constriction has been caused by infolding an ulcer at the pylorus, the chances of recovery are increased if a gastro-enteric anastomosis can be done immediately.

Mr. Evans has put his views very moderately and wisely, and I find myself almost in agreement with his carefully guarded indications as laid down in the last paragraph of the article.—I am, etc.,

London, W.1, Feb. 1st.

V. ZACHARY COPE.

Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

The King's Speech.

PARLIAMENT was opened on February 2nd by the King in state. The Speech from the Throne announced that proposals would be made for effecting reduction in public expenditure. Ministers were considering proposals for improving housing in country districts and in the congested areas of towns, and bills would be submitted this session, if time permitted, to hasten the removal of the worst defects. The Government hoped to consolidate the main statutes relating to local government. If time permitted bills would be laid before Parliament dealing with national health insurance, unemployment insurance, the control of road vehicles, and the position and powers of boards of guardians.

The debate on the Address in reply to the Speech from the Throne occupied the rest of the week, among the topics discussed being unemployment. Details of the Government's proposals for public economies were promised at an early date.

The Medical Committee of the House of Commons agreed to meet on February 3rd to discuss business and afterwards to dine together. Arrangements are being made to invite other members of Parliament to a meeting at which the medical view regarding unregistered practitioners will be explained. Questions are expected in the House on this subject, and lay members of Parliament propose to present a private member's bill incorporating schemes for the State recognition of osteopaths. A bill dealing with the regulation of opticians may also be introduced. Matters affecting the East African Medical Services may also be raised by questions on the Colonial Office vote.

Obituary.

CHARLES PLUMLEY CHILDE, B.A., F.R.C.S.,
Consulting Surgeon, Royal Portsmouth Hospital; President of the
British Medical Association, 1923-24.

The death at Monte Carlo of Mr. C. P. Childe, on January 30th, from heart failure following pneumonia and influenza, has come as a great shock to all classes of society in Portsmouth. In professional circles, in civic life, and to very numerous friends and acquaintances, his death and the suddenness of his passing have excited a sense of loss to which it is difficult to give expression.

Charles Plumley Childe, the elder son of the Rev. G. F. Childe, M.A. Oxon., Professor of Mathematics at the South

African College, and Assistant Astronomer of the Royal Observatory, Cape-town, was born, bred, and educated in South Africa, coming later to Cambridge University and King's College Hospital for his medical training. At the University of the Cape of Good Hope he won the Maynard scholarship and a university exhibition, and graduated B.A. with honours in 1877. He then entered Magdalene College, Cambridge, with a scholarship, and while at King's College Hospital gained a Warneford scholarship. In 1883 he obtained the M.R.C.S. Eng. diploma, in 1885 the L.R.C.P. Lond., and in 1900 the M.R.C.P. Edin. Early in 1886, at the age of 28, he started general practice in Southsea, being joined a year or two later by an old friend, Dr. Lister Wright, as a partner. To a man like Mr. Childe, however, the art and practice of surgery, with its more exact methods, made a stronger appeal than the routine of general practice, and he soon gave up the latter to devote himself entirely to surgery. He took the F.R.C.S. Eng. diploma in 1892, was appointed assistant surgeon to the Royal Portsmouth Hospital, and rapidly established the reputation of being one of the most brilliant and successful surgeons in the South of England. An account of the splendid work which he did at the Royal Hospital will more properly be afforded by one of his surgical colleagues, but no reference to his life would be complete without mention of the skill, great ability, and untiring personal service which he freely expended in bringing that institution to its modern standard of efficiency. When, in accordance with the age regulations of the hospital, he retired in 1923, he was appointed senior honorary consulting surgeon and chairman of the Committee of Management. It would be difficult to speak in too high terms of the enormous debt of gratitude which the public of Portsmouth owe to Mr. Childe for his life's work at the Royal Portsmouth Hospital. The same energy and skill were, during the war, devoted to the 5th Southern General Hospital, of which, as lieutenant-colonel in the R.A.M.C.(T.), he was for some time in charge.

Apart from his operative work the subject which above all others keenly interested Mr. Childe was the reduction of the cancer mortality rate. His books on this subject, *The Control of a Scourge*, published in 1906, and *Cancer and the Public*, issued last year, are well known in this country and perhaps even better known in America. In the latter he is rightly regarded as one of the pioneer workers in this direction, and he was gratified a month ago to receive an invitation, as one of the foremost European authorities, from the American Society for the Control of Cancer, to attend an "International Meeting of Cancer Experts," to be held in the United States in September next. Mr. Childe endeavoured with all the energy of which he was capable to make the public realize that cancer, in very many of the sites in which it occurs, is curable if the patient will only consult the surgeon at a sufficiently

early stage in the onset of the disease. He did his utmost to get out of the public mind the fatalistic idea that a diagnosis of cancer was equivalent to a death warrant, and, when he became a member of the local health authority, was instrumental in securing the issue by the Portsmouth Health Department of an educational leaflet on the subject. Similar leaflets based on this have since been issued by many other health authorities in the country.

Mr. Childe was proud of his profession and always took the keenest part in forwarding its interests. He was a willing and able worker in connexion with all local medical societies, and he became particularly identified with the British Medical Association. He was president of the Southern Branch in 1912; chairman of the Portsmouth Division in 1914, having previously been honorary secretary and treasurer for three years, and clinical secretary since 1910. At the Annual Meeting at Portsmouth in 1899 he was secretary of the Section of Obstetrics and Gynaecology, and when the Association met again there in 1923 his colleagues did him the honour of electing him

President. He devoted himself heart and soul to the task of making the Annual Meeting a success; and in the following two years, as President and immediate Past-President, he was a regular attendant at the Council meetings in London. In July last he was elected a vice-president of the Association.

In addition to his work at the Portsmouth Royal Hospital, Mr. Childe was surgeon to the Hants and Isle of Wight School for the Blind, and had in former years held the offices of surgeon to the Home for Sick Children at Southsea, senior surgeon to the South Hants Medical and Surgical Home for Women, and anaesthetist to the Portsmouth and South Hants Eye and Ear Infirmary. His writings on cancer have already been mentioned. He was the author also of a small practical manual on *Surgical Nursing and Technique*, and during the past twenty years he contributed a number of papers, mostly dealing with abdominal operations, to the columns of the *BRITISH MEDICAL JOURNAL*.

[Elliott and Fry, London.

Charles P. Childe

In 1912, at the urgent request of his medical colleagues, Mr. Childe consented to take a part in municipal affairs, and was returned a member of the Portsmouth Town Council by the electors of the Mile End ward of the town. As a member and, since 1919 as chairman, of the Health Committee his professional knowledge has proved of immense value to the borough. Both in committee work and in the council chamber he displayed the same mastery of the subject under discussion as was seen in his professional work. His judgement upon a subject was formed only after making himself thoroughly conversant with all the factors concerned; then, having made up his mind as to the course that he should take, he pursued it with unswerving directness. Though a facile and ready speaker, he was never prolix; he spoke straight to the point, and the orderly marshalling of his facts and the clear logical expression of his views seldom failed to carry conviction. To the very difficult problems in connexion with the housing question he gave much thought; he made himself acquainted with all its aspects, and both in committee and in the council worked his hardest to relieve the stress and hardship due to house shortage. Although he was not able, unfortunately, on all occasions to carry the council with him so far as he sometimes desired, there can be no doubt that the improvements in the housing conditions of Portsmouth to-day are mainly due to his efforts. For his presidential address to the British Medical Association two years ago he chose, appropriately, the subject of environment and health, which he handled with characteristic vigour and outspokenness. No one on the town council was listened to with more attention, and none more enjoyed the respect of his colleagues; had his ambition lain in that direction, it is no secret that he might have occupied the highest municipal honours which his fellow councillors could confer upon him, and it has been a matter of regret to many that he felt that his professional duties did not leave him the time necessary to undertake the duties of that office.

In person slight of build, Mr. Childe was a man of unbounded energy. He was a keen sportsman, and there were few important contests at Lord's, Twickenham, or Wimbledon at which he did not endeavour to be present. For some years past he had been an enthusiastic golfer, and his memory among medical golfers will be kept green by the Childe Challenge Cup, which he presented to the Association. C. P. Childe was essentially an all-round man. Whatever he undertook to do he put into it his whole heart, and if there was one outstanding characteristic of the man it was his thoroughness. A man of wide interests, of exceptional professional attainments, a great public servant, and a charming companion, the passing of "C. P." leaves a blank which can never be filled.

A. M. F.

We are indebted to Mr. A. Bosworth Wright, surgeon to the Royal Portsmouth Hospital, for the following tribute to his friend and colleague: By the death of C. P. Childe, Portsmouth has lost one of her most

useful and distinguished citizens, and the medical profession an outstanding personality. Childe had practised in Southsea for over thirty-five years, first as a general practitioner and later as a surgeon. He worked for, and passed, his Fellowship during the time he was in busy general practice—no small attainment. He was appointed to the assistant staff of the Royal Portsmouth Hospital in 1891, and at once began to modernize the hospital, and it was mainly on his initiative that a new theatre and wards were built. His masterful personality showed the way and lesser lights were content to follow, helping when they could. But it is not of Childe as a surgeon that I would write—great though he undoubtedly was—but rather as a man and a friend. He was not an easy man to understand, and those with a superficial knowledge rarely did him justice. He had a mind that saw

things so clearly that he was apt to be impatient with those who could not always see with him, but he was always fair and just. He was essentially a strong man, a man of few words; but under an iron reserve he could be very human and very kind. He admired courage, but fear irritated him. He was a happy warrior: he loved a fight. His seat on the town council was for an industrial ward, which Labour had marked for its own, and every three years he fought a fierce fight and won by ever-increasing majorities. His honesty, his fearlessness, and his power of clear exposition won for him a position of great influence on the council. Thoroughness was one of his outstanding characteristics; whatever he did he did well and saw it through; compromise was to him weakness. As a friend and colleague he was always loyal, resourceful, and stimulating, always accessible, always willing to help. He had a powerful and steady influence on the medical thought of the town in all times of

stress, and it is here that his loss will be most widely felt. To us, his friends who are left, our loss seems irreparable.

WILLIAM HISLOP MANSON, M.A., M.D., F.R.F.P.S.,
Surgeon to the Eye Infirmary, Glasgow.

Dr. W. HISLOP MANSON, while in the performance of his duties in the operating theatre of the Glasgow Eye Infirmary on January 28th, had a cardiac seizure and died almost instantaneously. His death, with such startling suddenness while he was apparently in the enjoyment of perfect health and at the early age of 43, has come as a great shock to his medical colleagues and to all who knew him.

He was educated at Glasgow High School and Glasgow University, and took the degree of M.A. in 1901 and graduated M.B., Ch.B. in 1906; four years later he received the degree of M.D. with commendation. He was admitted a Fellow of the Royal Faculty of Physicians and Surgeons in 1912. After graduation he held resident posts in the Royal Infirmary, the Glasgow Eye Infirmary, the Royal Maternity Hospital, and the Ruchill Fever Hospital. Being early attracted to ophthalmology he was appointed

to the staff of the Eye Infirmary in 1911. As an officer in the R.A.M.C.(T.) he was mobilized on the outbreak of war, and volunteered for foreign service, which took him to Gallipoli, Salonica, Egypt, and the Russian front; he suffered from several of the tropical illnesses incidental to service in the Levant. Soon after the armistice he was appointed visiting surgeon to the Eye Infirmary, and in 1920 was elected to the chair of ophthalmic medicine and surgery at the Anderson College of Medicine. At both these centres, by his practical methods and his enthusiasm as a teacher, he soon gathered round him a large class of students.

When the British Medical Association met in Glasgow in 1922 he took an active part in the work of the Annual Meeting, and acted as local honorary secretary of the Section of Ophthalmology.

He was a man who made many friends and few, if any, enemies. Possessed of a buoyant disposition and a genial and humorous manner, he was not readily perturbed. During a friendship that has existed for over twenty-five years the writer of this note has never seen him lose his temper. He was married soon after the outbreak of war, and leaves a widow and one son, to both of whom he was devoted.

CHARLES EDWARD ROBERTSON, M.D.,
Glasgow.

WE have to record with regret the death of Dr. Charles E. Robertson of Crosshill, Glasgow, who died on January 16th. Born in Ayrshire in 1850, he qualified as a teacher and taught for a number of years before taking up the study of medicine. He graduated M.B., C.M. at Glasgow University in 1888, and soon after settled in general practice in the south side of Glasgow, where he spent the rest of his life. He proceeded to the M.D. degree in 1898.

A man of varied attainments and many interests, he was early attracted by medical politics, and for many years was an outstanding figure in public medical life in Glasgow. He was a justice of the peace, a governor of the Victoria Infirmary, and a member of the Glasgow Burgh Insurance Committee from its inception. He was also an active supporter and office-bearer of the Southern Medical Club and the Southern Medical Society.

In the British Medical Association Dr. Robertson was, in turn, chairman of his Division (Glasgow Southern), president of the Glasgow and West of Scotland Branch, member of Council, and a representative for over twenty years. During his two periods of service upon the Central Council of the Association he was most regular in his attendance at the meetings in London. He never spared himself in the public service. Whatever cause he espoused, he advocated it strenuously and effectively; his pertinacity in controversy commanded the respect, even as his bonhomie earned him the regard, of his fellows. He is survived by his widow.

JOHN H. ALEXANDER, M.B., C.M.,
Late of Dundonald, Ayrshire.

MANY of our readers whose recollections of Glasgow University go back to the late seventies of last century will have shared our regret at the announcement last week of the death of Dr. John H. Alexander, which occurred at Colinton, near Edinburgh, on January 20th.

Owing to failing health Dr. Alexander had to relinquish practice some years ago, but in earlier life he had been associated with, and ultimately succeeded, his father, Dr. William Alexander, whose reputation as a singularly gifted and trusted physician extended far beyond the picturesque little village of Dundonald in Ayrshire where he resided. During a long life of active work Dr. Alexander, sen., had built up, what nowadays seems scarcely possible, a consulting practice from a rural centre, and it was under such auspices that his son began his medical work. But after a few hopeful years progressive impairment in health set in, and ultimately led to his retreat from practice.

It was not in his nature, however, to stand aside and look at life solely as a spectator, and for some years afterwards he reverted to an early interest in applied physics, and delivered several courses of lectures on electrical

engineering to the evening classes held in Kilmarnock Academy under the auspices of the local education authority. Ultimately even this proved more than his failing strength permitted him to undertake, and some twelve years ago he removed to Edinburgh, and then to Colinton, where he died.

Although much of his life was thus passed in retirement, his interest in the progress both of the medical and of the mechanical sciences remained active.

Almost by instinct he was an engineer, and a volume on *Model Engine Construction*, published by Whittaker and Co., went through two editions; while another on *Elementary Electrical Engineering* reached its fifth edition in 1925. He issued another volume on *Model Balloons and Flying Machines*, and constructed a model aeroplane which found a place in one of the Glasgow International Exhibitions in the early days when knowledge of heavier-than-air machines was still in its infancy. He also published a series of newspaper articles on mechanical inventions from before the Christian era till the present day, and, as an illustration of another aspect of his many interests, he wrote a volume of *Gleanings about Christ and Early Christianity*.

Patience and charitableness ran through his life like silver threads relieving the shadows of his physical weakness, and his life was a bright example of what may be accomplished amidst such limitations. He leaves a widow and two daughters, to whom deep sympathy will be extended.

Dr. WILLIAM PERCY HILLIAM of Wyke, near Bradford, died on January 14th. He was the eldest son of the late Captain Thomas Hilliam, and was born at Willesby Hall, Spalding, in 1859. From Malvern College he went to the University of Edinburgh, and continued his medical studies at St. Thomas's Hospital Medical School. He took the diploma of L.S.A. in 1893, and that of L.M.S.S.A. in 1907. After serving as assistant to a medical practitioner in Sheffield, he commenced practice at Wyke some thirty-five years ago. He was a member of the Bradford Division of the British Medical Association and of the Bradford Medico-Chirurgical Society, and a Fellow of the Royal Society of Medicine. Dr. Hilliam is survived by his widow and one son.

Dr. GEORG THIEME, founder of the *Deutsche medizinische Wochenschrift* and head of the publishing department, has recently died at the age of 65. He received the degree of doctor *honoris causa* from the Leipzig faculty of medicine on the occasion of the fiftieth anniversary of the journal in 1924.

The deaths of the following eminent foreign medical men are announced: Dr. H. Fehling, formerly professor of clinical gynaecology at the University of Strasbourg, at the age of 78; Dr. Edouard De Smet, honorary professor of Brussels University, aged 83; Dr. Georg Puppe, director of the Institute of Medical Jurisprudence and formerly dean of the medical faculty of Breslau, aged 58.

The Services.

DEATHS IN THE SERVICES.

Colonel Herbert Enslace Cree, Army Medical Staff (ret.), died suddenly of heart failure, while travelling on the Metropolitan railway, on January 25th, aged 66. He was born at Budock, Cornwall, on November 27th, 1859, was educated at the Middlesex Hospital, and took the L.S.A. in 1882 and the M.R.C.S. in 1883. Entering the army as surgeon on August 1st, 1885, he became lieutenant-colonel after twenty years' service, and was promoted to colonel in the long war promotion list of March 1st, 1915, retiring on December 26th, 1917. He served in the Chitral campaign of 1895, with the relief column, gaining the Indian frontier medal with a clasp; in China in 1900, when he was mentioned in dispatches in the *London Gazette* of May 14th, 1901, and received the medal, and in the recent great war.

Lieut.-Colonel Hazlett Allison, Madras Medical Service (ret.), died on November 15th, 1925, aged 74. He was born on April 30th, 1851, at Drumraha, Ireland, and was educated at Queen's College, Belfast, graduating as M.D. and M.Ch. in the Queen's University in 1873. Entering the I.M.S. on September 30th, 1883, he became surgeon lieutenant-colonel after twenty years' service, and retired on December 23rd, 1903.

Universities and Colleges.

UNIVERSITY OF LONDON.

DR. ANDREW BALFOUR, C.B., C.M.G., and Dr. M. E. Delafield have been appointed representatives at the Imperial Congress of the Royal Sanitary Institute to be held in London in July, 1926, to celebrate the jubilee of the institute.

The degree of D.Sc. in cytology has been conferred upon Mr. R. J. Ludford for a thesis entitled "Studies in normal and pathological cytology," and other papers.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.

AN ordinary comitia of the Royal College of Physicians of London was held on Thursday, January 28th, when the President, Sir Humphry Rolleston, Bt., was in the chair.

The minutes of the Censors' Board were read and confirmed.

The late Queen Alexandra.

The address of condolence from the College to H.M. the King on the death of Queen Alexandra was read, together with the official reply received from the Home Office.

Membership.

The following were admitted to the Membership:

Douglas Kinchin Adams, M.D.Glasg., George Allison Allan, M.D.Glasg., John Ford Anderson, M.D.Aberd., George Vincent Ashcroft, M.D. Manch., Hugh Barber, M.D.Lond., L.R.C.P., Harry Beddingfield, D.S.O., M.B.Edin., John Anthony Birrell, M.D.Lond., L.R.C.P., Ernest Bulmer, M.D.Edin., Ernest William Henderson, M.D.Lond., L.R.C.P., Ryan Frost, M.B.Lond., Gwenvyn Hall, M.B., L.R.C.P.

Stanton, M.B.Melb., Alexander Jarvie Hood Stobo, M.B.Sydney, Selwyn Edward Tanner, M.D.Lond., L.R.C.P., John Thomas Patrick Tansey, M.B.Sydney, Norman Bruce Williamson, M.D.Edin., Claude Wilson, M.D.Edin.

Assistant Registrar.

The President consulted the College as to the desirability of appointing an Assistant Registrar, and Dr. R. O. Moon was nominated for appointment at the next meeting.

Licences.

Licences were granted to the following candidates, who had passed the required examinations and conformed to the by-laws and regulations:

P. W. A. Agnew, S. A. Antoun, N. A. Arnold, A. Ashworth, A. L. Banks, C. M. Barker, L. H. Belcher, R. J. I. Bell, S. B. Benton, F. Bernstein, M. Bomze, *Elsie Boyton, R. Broomhead, A. Byrne-Quinn, *Irene F. Callender, A. L. Canby, De L. Carey, S. Chazen, H. Childs, J. H. Chitty, J. H. Clapp, A. Clark, G. C. W. Clarke, H. N. Collier, *Violet H. Cumber, R. V. Cooke, W. F. Cooper, A. R. Cox, S. T. Davies, T. W. Davies, T. E. Davies, *Hilda C. Dean, A. E. de Fonseca, *May, W. de Livera, G. C. Dewes, H. V. Dicks, *Mary G. H. Dickson, *Margaret H. Duncan, G. H. Dymond, *Elaine E. H. Earengay, R. W. B. Ellis, D. C. McC. Ktles, J. Evans, B. Fink, C. W. Flemming, T. D. W. Fryer, S. W. Gabbe, S. P. Gawne, P. Gibbin, *Dorothy Godden, P. J. Gonsalves, A. P. Gorham, *Aenes H. Gray, D. P. Gray, *Margaret K. Green, W. H. Green, C. R. M. Greenfield, L. A. N. Greenway, B. J. Griffiths, A. A. M. Groot, A. Gross, F. P. Guilloyle, K. H. Hadley, R. N. Hall, C. W. Harrison, L. Hartston, H. G. Harvey, J. P. Heldwell, T. R. Hill, R. L. Holt, B. B. Hosford, *Mary H. McC. Huggett, N. C. Hypper, D. E. Iago-Jones, R. J. Isaac, G. L. C. Jones, T. Jones, J. Kahanas, J. A. Kerr, *Hilda M. King, R. H. Knight, P. H. Knowles, T. P. Lalonde, F. J. L. Lang, F. W. Law, D. F. Lawson, R. L. J. Le Clezio, *Margaret E. Ledger, *Anne T. Leigh, E. A. Lewis, R. A. V. Lewys-Lloyd, *Leonora M. K. Lines, T. M. Ling, *Edith M. Little, G. F. H. McCormick, G. L. M. McElligott, L. J. McGregor, *Evelyn T. D. MacLagan, A. J. McMillan, P. Malpas, *Ruth E. Mansfield, *Mary A. Marshall, Jorwerth O. Martin, S. R. Matthews, H. R. R. Mavor, W. Mayne, S. Mellins, R. H. Metcalfe, G. C. Milner, J. Mintzmann, F. E. Montague, P. Morton, M. Mundy, D. H. P. M. Q. Mytebreest, C. B. Nicholson, J. R. P. Norman, G. F. Oakden, E. J. O'Keefe, J. E. J. Palmer, C. H. Parker, G. E. G. Peirce, H. A. Pictou, H. P. Pieris, N. R. Pooler, W. G. Porter, D. C. Price, *Winifred E. Probert, D. M. Pryce, *Muriel A. Push, F. W. F. Purcell, *Nellie L. Pyman, J. H. Randall, *Marjorie D. Reddan, *Margaret G. P. Reed, H. G. St. M. Rees, J. L. Reeve, A. M. Rhydderch, O. Richardson, L. Roberts, *Victoria A. Roberts, D. J. L. Routh, *Audrey E. Russell, J. W. Schabert, *Gitta Schwefel, F. L. G. Selby, T. H. Seller, D. W. Seth-Smith, A. de M. Severne, W. D. Sheldrake, *Alice Sney, *Tait, *Thorpe, G. O. Tippet, R. S. Tooth, *Rose A. H. Traill, R. M. Walker, L. H. F. Walton, H. D. Weatherhead, *Janet Welch, *Violet M. Weston, E. A. White, J. E. B. Williams, J. H. Williams, H. Williamson, D. B. Wilson, *Jessie Wiltshire, *Ada R. Winter, J. Wiseman, *Joan Worsfold, *Dorothy E. Wright.

* Under the Medical Act, 1876.

Diplomas in Special Subjects.

Diplomas in the subjects indicated were granted jointly with the Royal College of Surgeons to the following:

D.P.H.—P. L. T. Bjorkgren, M. A. B. Brito-Mutunayagam, Elman, W. D. Forgrave, Janet M. Gillis, W. O. Pou, A. DIPLOMA IN TROPICAL MEDICINE AND O. F. Conoley, R. A. Mansell, C. H. H. Robertson. DIPLOMA IN PSYCHOLOGICAL MEDICINE.—N. A. Albiston, H. E. August, A. A. Bell, Eleanor M. Creek, J. H. Cuthbert, H. S. Forbes, T. R. Forsythe, E. F. Hewitt, R. M. Macfarlane, J. McGarvey, E. D. T. Roberts, F. C. M. Taylor. DIPLOMA IN OPHTHALMIC MEDICINE AND SURGERY.—Esmé V. Anderson, J. B. Baird, A. Bajaj, D. P. Billimoria, C. G. H. Blakemore, Victoria E. Brander, J. A. Browne, A. Caddy, H. R. Dive, R. R. Garden, P. N. Gokhale, G. McN. Hargreaves, K. R. Hill, A. MacLach, J. Marshall, J. N. Piplani, Portia K. Taylor, Doris Todd, S. T. Wong. DIPLOMA IN LARYNGOLOGY AND OTOTOLOGY.—P. V. Cherian, J. M. Damany, W. J. McNally, N. C. Ramechandani.

Psycho-analysis.

Dr. Major Greenwood moved the following resolution:

The College, taking note of the fact that members of the medical profession have stated in the public press that the practice of certain methods of diagnosis and treatment generally known as "psycho-analysis" is open to grave objections, requests the President to appoint a committee to inquire into the truth of such statements, and to report what instructions, if any, it may to impose upon the use of these methods by Fellows, Members, and Licentiates of the College.

This was not carried.

Appoints.

On the nomination of Jollier, Dr. S. W. Wheaton, Dr. J. S. Fairbairn, and Dr. C. S. Martin were elected Councilors to take the place of Dr. W. S. Lazarus-Barlow, Sir John Broadbent, Dr. T. W. Eden, and Sir George Newman.

On the nomination of the Council, Sir Francis Champneys was reappointed a representative of the College on the Central Midwives Board for England and Wales.

Dr. Drewitt was reappointed representative of the College on the committee of management of the Chelsea Physic Garden for four years, and Sir Thomas Barlow a representative of the College on the executive committee of the Imperial Cancer Research Fund.

Dr. Arthur Shadwell was appointed a representative of the College on the Queen Victoria Jubilee Institute for Nurses.

The resignation of Mr. Bryan Farrer as junior standing counsel to the College was received. The President nominated Mr. Dighton Pollock for election. It was directed that a letter should be sent to Mr. Bryan Farrer thanking him for his services during a quarter of a century.

The resignation of Sir Dyce Duckworth as representative governor of the University of Liverpool was received. The Council expressed its high sense of the services he has rendered. Dr. Abram was appointed in his place.

Lecturers.

The President announced that he had appointed Dr. F. G. Crookshank to deliver the Bradshaw Lecture for 1926, and that the Council had appointed Mr. W. F. Dearden, M.R.C.S., L.R.C.P., to be Milroy Lecturer for 1927.

Licentiates and Diplomates in Special Branches.

The Registrar moved for the first time that by-law 160 be amended to read as follows:

A list of all Fellows and Members of the College, and a list of the new licentiates and diplomates in the special branches of medicine admitted during the preceding twelve months, with their places of residence, shall be submitted to the Censors' Board for England, Scotland, and Ireland.

Reports.

The following reports from the Committee of Management, dated December 23rd, 1925, were received and adopted:

The Committee of Management recommend that certain universities which were removed in the year 1918 from the list of recognized places of study, and graduates of which are admissible to the Final Examination of the Board, be now reinstated in the list, as follows:

Germany: University of Bonn, University of Breslau, University of Göttingen, University of Halle, University of Jena, University of Königsberg, University of Leipzig, University of Marburg, University of Münster, University of Rostock, University of Strassburg, University of Tübingen, University of Würzburg.

German universities.

The Committee of Management recommend that the following additional clauses be added in chapter I of the Regulations of the Examining Board in England, namely:

X. Any representation which a candidate may desire to make with regard to the conduct of his examination must be addressed to the secretary, and not, under any circumstances, to any of the examiners.

XI. The Committee of Management may refuse to admit to examination or to proceed with the examination of any candidate who infringes or is considered to infringe the regulations of the Board, or who is considered to be of such a character as to be prejudicial to the proper conduct of the examination.

In accordance with the conditions relating to special diplomas laid down by the Royal Colleges in April, 1920, the Committee of

THE late Sir Richard Douglas Powell, Bt., Physician in Ordinary to Queen Victoria, King Edward, and King George, who died on December 15th last, aged 83, left estate of the gross value of £43,679 with net personality £41,769. He directed his executors to burn or destroy all his case books and letters relating to his private patients.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the BRITISH MEDICAL JOURNAL must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the JOURNAL, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBERS of the British Medical Association and the BRITISH MEDICAL JOURNAL are MUSEUM 9361, 9362, 9363, and 9364 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR of the BRITISH MEDICAL JOURNAL, Aitiology Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westcent, London.

MEDICAL SECRETARY, Medicisera Westcent, London.

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 4361 Central).

QUERIES AND ANSWERS.

LEAD SALTS IN CANCER.

COLONEL G. F. ROWCROFT (Bangalore) writes: I have received several issues of the JOURNAL since that for November 28th, 1925, containing (p. 1040) Dr. G. C. Belcher's note on the use of lead for cancer, but so far no one has remarked on the dose he advocates, 1½ grains daily for a week, and then twice the amount, which he describes as "heroic doses." I can hardly imagine that 1½ grains would have much effect.

ENLARGED VEINS ON THE CHEST IN CHILDREN.

DR. J. LEWIS THOMAS (Newport, Mon.) writes: Can we depend upon the presence of enlarged veins in the infraclavicular region as an aid to diagnosis between cardiac disease and tuberculosis, when signs and symptoms, together with the radiograph, give uncertain testimony? The von Pirquet test, with repeated negative results in such cases, warrants a decision in favour of the former; and this has been supported by the history of patients during school age and adolescence. In the congeries of venules in the suprascapular regions we have a different and less definite picture.

"JOGRAJ."

DR. J. D. DHURV (London), with reference to the inquiry printed on December 26th, 1925 (p. 1252), writes to say that this preparation is used for chronic inflammatory swellings. He is not sure whether it contains iodine, but it contains some Indian herbs, and its chief constituent is a gum resin. The original formula can be found in *Sarangdhar Samhita*, a classical Sanskrit pharmaceutical book.

LETTERS, NOTES, ETC.

BURNS FOLLOWING THE USE OF INFLAMMABLE HAIR COMBS.

DR. T. STENNER EVANS (Fochriw, Glamorgan) writes: The letters published recently in the BRITISH MEDICAL JOURNAL on this subject prompt me to place on record an account of a similar case. Some months ago I was called to see a young woman whose scalp had been severely burnt. Her relations stated that she had been standing near a fire whilst rubbing into her hair an alcoholic lotion. She then fixed into her hair some celluloid combs, which almost immediately burst into flame. Her hair and scalp were severely damaged before the relatives could remove the combs. The scalp has now healed, but there remains a large adherent painful scar, in which nearly all the hair follicles are destroyed, and on which, consequently, very little hair is likely to grow. The increasing number of such accidents serves to accentuate the danger of wearing inflammable hair combs, and, in my view, the manufacture of such articles should be strictly prohibited.

TREATMENT OF VARICOSE VEINS.

DR. J. NISSEN DEACON (London), whose previous letter appeared on September 26th, 1925 (p. 583), writes further with reference to the Bagnolles treatment of varicose veins:—I have since had experience of the home treatment for women, which is as follows:

Having visited the spa in June or July, the patient waits until September or October, and then lies quietly and completely submerged in a bath almost full of water at 97° F., to which has been added 20 oz. of sodium bicarbonate and 4 oz. of alum. The bath is taken twice a week before breakfast and lasts for twenty minutes. For half an hour after the bath she lies flat, and breakfast in bed follows, the rest being continued for an hour or so afterwards. For the ten days following the termination of the menses 10 minims of a 1 in 1,000 solution of adrenaline are taken by the mouth before breakfast, lunch, and dinner (I have seen this cause indigestion, and believe oral administration to be useless). For the next ten days the patient takes phlebosine fem. (H. Carrion and Co., Paris), one tablet before lunch and dinner. This is a polyglandular product containing small amounts of thyroid and other extracts (personally, I prefer hormotone: Carnrick). During the menses baths and all medications cease. This course is continued for three months, alternating with a period of two months' cessation of treatment, so that by the time the patient is due to return to Bagnolles she will have completed two courses and two rest periods. During alternate months, and irrespective of "courses" and "rests," she must gently and centripetally massage her legs at night when in bed. Hot-water bottles must be put out of the bed when entering it. When sitting the leg should be supported by a low padded stool; special stools are sold in Bagnolles. In subhyrotic and vagotonic women I have seen definite improvement in the general condition follow this régime, although the veins may appear unaffected. This is probably due to stimulation of the sympathetic nervous system by the thyroid extract. The detail of such a "cure" doubtless impresses some patients, who feel better in consequence of knowing that something is being done. If the administration of thyroid is controlled, and withheld when necessary, the "cure" can do no harm, and almost becomes an occupation for leisured people!

POTASSIUM CHLORATE IN CANCEROUS ULCERATION.

DR. T. M. ALLISON (Newcastle-on-Tyne) writes: In carcinoma the pain appears to be due to one of two causes—pressure or ulceration. For the pain of pressure morphine alone seems to give relief; but for the pain and sepsis of ulceration, in any part of the body, may I suggest the use in large quantities of potassium chlorate? By large quantities I mean doses starting with 10 grains three times a day and going up to the limit of tolerance. I have seen no ill effects from 50 grains or more three times a day in milk (sweetened) or in chloroform water. In some cases the results are striking. I have seen a case of cancer of the cervix with vaginal ulceration clear up in a remarkable way, the patient dying later of peritonitis, but the fever, bleeding, and pain practically disappeared. In another case of inoperable cancer of the rectum, where the ulceration was verified *post mortem*, the patient was quite unconscious of anything but slight discomfort at times, and there was no septic absorption and no cachexia. If one can relieve pain and avoid sepsis, and convert death from distress into death from painless hæmorrhage—as in the latter case—it is a step, if only a small one, in the welfare of the patient.

THE DEATH OF JOHN KEATS.

MR. W. A. MAGGS (Northam, North Devon) writes: The delightfully written and lately published *Life of Keats*, by Amy Lowell, gives many details of the illness of this great poet. Keats, accompanied by his buoyant and devoted friend Severn, reached Rome on November 17th, 1820, and went into lodgings in the Piazza di Spagna. The following extract from the book mentioned may be interesting to your readers:

"... the landlady of the apartment, who had notified the police that a man with consumption was dying in her house. Long before the English doctors had found out that tuberculosis was a contagious disease the Italians were convinced of the fact, and by their law everything in the room occupied by a tuberculous patient, even to the very wallpaper, must, after his death, be burnt. Now both Severn and Dr. Clark thought it would cheer Keats up to move him from his bedroom to the sofa in the sitting room for a few hours. In the sitting room were his and Severn's few books, the hired piano, Severn's painting materials—in short, everything of value which the friends possessed. All these things would be destroyed if it came to the knowledge of the police that Keats had been carried into the room."

Keats died in these apartments on February 23rd, 1821, and the communication referred to was made a few weeks previously.

A DISCLAIMER.

DR. S. HARDY KINGSTON (Clifton, Bristol) writes to disclaim all responsibility for references in the public press to a meeting of the local Branch of the British Medical Association, in which his name occurs. The matter which appeared was published without any authority from him.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 37, 38, 39, 42, and 43 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 40 and 41.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 51.

Purvis Oration

ON

THE SURGERY OF MALIGNANT DISEASE OF THE PHARYNX.

DELIVERED BEFORE THE WEST KENT MEDICO-CHIRURGICAL SOCIETY ON DECEMBER 11TH, 1925,

BY

WILFRED TROTTER, M.S.LOND., F.R.C.S.ENG.,
SURGEON, UNIVERSITY COLLEGE HOSPITAL.

(With Coloured Plate.)

WHATEVER may be our hopes about the discovery in the treatment of malignant disease of methods more specific and less harsh, surgical operation must be admitted to be the most useful and trustworthy means we now possess. The extension of the field to which it can be applied and the increase in the refinement with which it can be used are therefore among the most important duties of the surgeon. The development of the operative treatment of malignant disease in whatever department is not, however, a matter only concerned with surgical technique, but is equally dependent on pathological and clinical principles, and therefore has a general as well as a more special interest. It is for this reason that I have ventured to choose for my subject a branch of surgery which may at first sight seem to promise little but narrow technicalities, for I hope to show that it has some relations that concern us all in whatever branch of our art we may practise.

At this point I may perhaps be allowed to say a few words about my personal connexion with the subject, and in justification of the hope that my experience in it may have included some aspects that are not of common knowledge. In some Hunterian Lectures given in 1913 I laid down certain principles which had already proved useful in the treatment of malignant growths of the pharynx and tried to define the chief clinical generalizations that can be made about the disease in question. In the ensuing twelve years one's experience naturally has been largely added to. The steady increase of experience, while it has not perhaps made any changes in practice that amount to alterations of principle, has in this considerable lapse of years allowed of such an accumulation of changes in the technical detail of treatment that the lectures of 1913 no longer represent what is, in my judgement, the best we can do for the unfortunate sufferers from carcinoma of the pharynx. As my treatment of the subject on this second occasion of dealing with it is to be in the nature of a revision rather than a primary exposition, I shall hope to be able to keep in sight the aspects of more general interest that it possesses and to pass over its minor technicalities.

There are two further limitations I shall venture to set upon my handling of the material I have to put before you. First, I shall deal only with malignant disease of that part of the pharynx which is called by anatomists the laryngeal part. This includes the lower half of the length of the tube, and excludes matters like growths of the tonsil, which are more or less familiar to all, and growths of the naso-pharynx, which constitute a group having very different pathological relations. Limiting ourselves to the laryngeal pharynx we shall be concerned with two groups of cases—the growths about the upper opening of the larynx (epilaryngeal group), and the growths of the post-ericoid region (hypopharyngeal group). In both these groups we are concerned only with the squamous epithelioma. The second limitation I shall venture to set will be in the avoidance of statistical statements. Where experience is necessarily small—and the total number of the cases in question that I have ever seen, much less operated on and followed up, must probably be limited to a few hundreds—statements in figures are apt to possess more the air of authority than the substance of it, and to put more responsibility on the person who observes and classifies the facts than he may be competent or willing to

assume. These considerations are even stronger when the subject under inquiry is a changing and growing one, and as such I have always regarded the surgery of the pharynx. I shall therefore avoid numerical evidence in supposed confirmation of the conclusions I come to, and shall allow these to depend on a judgement that in the circumstances cannot perhaps be regarded as erring characteristically in the direction of haste.

THE GENERAL CHARACTERS OF MALIGNANT DISEASE OF THE PHARYNX.

It has commonly happened in the evolution of medicine that when a certain part of the body has come within surgical access, this mere fact has quickly reacted on the pathology and symptomatology of the part in an unexpectedly fertilizing way. This sequence, which we are all familiar with on the great scale in the cases of the abdomen, the chest, and the brain, has shown itself with precision in the minor example of the pharynx. As soon as it became evident that in the operation of lateral (trans-thyroid) pharyngotomy we have a means that gives easy and adequate access to the laryngo-pharynx and allows satisfactory treatment of a large number of the growths found there, it began also to be evident that our clinical and pathological knowledge of the early phases of malignant disease in this situation could and must be largely extended and clarified. We found that there are characteristic starting-points for the disease, that there are variations in type and progress, and that all these facts have a direct and practical bearing on operability and on post-operative prognosis. It is to the conclusions derived from such observations that I am particularly anxious to call your attention.

(a) *Frequency.*—Malignant disease of the laryngo-pharynx is not at all rare. In my opinion the disease is not very much less common here than it is in the mouth or oesophagus, so that our subject must take its place among the great primary groups of malignant disease the incidence of which is favoured by some local condition of normal life. Any attempt to make an exact statement of its frequency is quite useless, because even yet relatively few cases of growths in the cervical alimentary tract are submitted to exact diagnosis, and because the clinical record of cases is confused by the description of an indefinite number as "extrinsic carcinoma of the larynx." Whatever the exact figure may be, there can be no doubt at all that the disease is common enough frequently to escape diagnosis for many months. Its position in relation to diagnosis is like that of rectal carcinoma; it is common, its symptoms may well be those of much commoner trivial diseases, and to exclude it involves an examination that is rarely difficult is often a little troublesome. Some such comfortable diagnosis as that of "relaxed throat" is therefore apt to tempt our less conscientious moments.

(b) *Rate of Progress.*—Epithelioma in this region does not usually progress with great rapidity, and there is generally after the first appearance of definitely suspicious symptoms a period of several months during which the case is still operable. There is one very important factor which must always be allowed for in determining the apparent extent and progress of these growths, and that is the influence of sepsis. Sepsis in the pharynx and oesophagus is determined by the teeth, and, it must be added, not so much by their condition as by their presence. It is by the comparison of the appearances of epitheliomata occurring in those with teeth with the appearances of such growths occurring in the edentulous that one is able to estimate the influence of sepsis in exaggerating the apparent extent and gravity of the lesion. The two most important facts that experience has established in this regard are, first, that a growth that seems hopeless may become obviously operable within a few weeks of the clearance of the mouth, and secondly, that in patients already edentulous epitheliomata are apt to run an insidious and relatively symptomless course for several months.

(c) *Incidence according to Sex and Age.*—Epithelioma of the laryngo-pharynx shows perhaps the most remarkable example known in the pathology of malignant disease of the primary seat of the tumour being determined by the

sex of the patient. It is a familiar fact that the post-cricoid or hypopharyngeal carcinoma is practically limited to women, while growths around the upper laryngeal opening (epilaryngeal carcinoma) on the one hand, and of the cervical oesophagus on the other, although not wholly limited to men, show a strong preference for that sex. In addition to being almost exclusively a disease of women, the post-cricoid carcinoma is peculiar in appearing at a relatively early age. The age at which it appears may be estimated as at least ten years younger than that at which the epilaryngeal carcinomata of men begin to be common. My experience suggests that carcinoma beginning definitely on the posterior pharyngeal wall belongs to the post-cricoid group as regards sex and age incidence. This is a comparatively rare type; it arises on the posterior wall well above the cricoid region, and often is directly visible through the mouth. It is interesting from its incomprehensible association in sex incidence with the post-cricoid growth, and it has a certain technical interest in demanding for its treatment an operation of special design.

Malignant disease of the laryngo-pharynx, then, although including an indefinite number of minor variations, falls naturally into two broadly defined main groups that we name for convenience epilaryngeal and hypopharyngeal. The differences as to sex incidence between these two go with clinical and therapeutic peculiarities, so that the natural classification is also one of practical value (Figs. 1 and 2).

GROWTHS OF THE EPI-LARYNGEAL TYPE.

These growths occur on and immediately around the upper opening of the larynx. The great majority of them occur in the male sex, and of cases of malignant disease of the laryngo-pharynx in that sex the great majority are of this type. They occur in men who have reached or passed middle age. Four common starting-points can be made out by the study of early cases; these are: (1) the epiglottis; (2) the aryepiglottic fold, especially toward its arytenoid extremity; (3) the lateral pharyngeal wall outside and away from the arytenoid; and (4) the pyriform sinus. When these starting-points are known a little experience will enable one from the laryngoscopic examination to estimate with some precision with which type one has to deal in a given case. The decision is important and worth an effort to attain, as it has a direct bearing on treatment and prognosis.

It may be stated at once that growths starting at any of the three points first mentioned (the epiglottis, the fold, the lateral wall) lend themselves to satisfactory operative treatment. At early and even moderately advanced stages a cure or freedom from the disease for many years can be looked for with reasonable confidence, without great operative dangers, and with no permanent mutilation or disability. The case is different with growths that start in the pyriform sinus. In this case the situation of the growth makes it symptomless in the early stages, and also leads to early involvement of the lateral wall of the larynx on the one hand, and of the thyroid cartilage on the other. It often happens, therefore, that by the time diagnosis is possible even an extensive and mutilating operation is of little use (Fig. 3).

Diagnosis.

I do not propose to discuss the finer shades of diagnosis among these types. The uses of practical work will be met if we know, first, when to suspect malignant disease of

the laryngo-pharynx; secondly, how to make a reasonably probable diagnosis of its presence; and thirdly, how to estimate in a general way the gravity of the case and the prospects of treatment.

In middle-aged and elderly men any kind of abnormal sensation persistently felt in the same part of the throat should be regarded seriously. The sensation may be a tickling; it may be that of a crumb or larger body of food

lodged in the throat; it may be a discomfort in swallowing saliva alone while there is no difficulty at meals. There is usually no pain in these early stages, no trouble in swallowing food, no alteration of the voice, except perhaps to a very finely discriminating ear, and no affection of the general health. Occasionally enlarged glands—not necessarily carcinomatous—appear very early. For this reason palpation of the cervical glands is an art that should be cultivated very carefully, and one should not be content to regard the glands as normal in a given case unless the patient has been examined lying down and with all the muscles of the neck relaxed.

Laryngoscopic examination is, however, of course the essential method. It must be admitted that malignant disease of the pharynx is overlooked rather often in its early stages. I am convinced that this is due to no difficulty in the diagnostic problem itself, but rather to the modesty of medical men in tending to regard the laryngoscope as an instrument always and only for the expert. It is perfectly true that to get a good view of the interior of the larynx, and especially of the anterior part of the vocal cords, is sometimes very difficult. There is, however, no need for this in the cases we are discussing. All that is necessary is to get an adequate view of the upper opening of the larynx and to estimate the mobility of the arytenoids. This is easy, and in the majority of cases demands no more than that the mirror should be used with a good light, some gentleness and patience, and a general idea of what one may expect to see.

There are three appearances to be on the look-out for when a growth of the epilaryngeal region is suspected: (a) an ulcer with a raised edge, which may, of course, be seen only in part, but of which the merest glimpse definitely caught is diagnostic; (b) a collection of muco-pus which the patient cannot get rid of by swallowing; (c) a fixed arytenoid. A fixed arytenoid, if much ulcerating growth can be seen, generally indicates a late stage of disease; if little ulceration can be seen it points to the dreaded pyriform sinus type. A freely movable arytenoid, even when the growth seems of formidable size, is always a favourable sign. (Plate, Fig. 1.) The amount of fungation of a growth is not necessarily a measure of its gravity; sometimes the pharynx seems filled by an ugly sloughy mass which at operation proves to be semi-pedunculated and arising from a relatively localized epithelioma.

GROWTHS OF THE HYPOPHARYNGEAL TYPE.

These growths occur in the narrow tubular part of the pharynx behind the cricoid cartilage. They are practically limited to women, and include the great majority of epitheliomata of the pharynx in that sex. They appear in the adult and middle-aged, and are not uncommon in the fourth decade. A remarkable feature of my experience of these cases is that the history given by the patient often shows that there has been some difficulty in swallowing for many years, and that on this slight disability the serious dysphagia has gradually supervened. Difficulty and awkwardness in swallowing are common complaints in

FIG. 1.—Distribution and sex incidence of epithelioma of laryngo-pharynx. The epilaryngeal group, the ordinary type occurring in men.

FIG. 2.—Distribution and sex incidence of epithelioma of laryngo-pharynx. The hypopharyngeal group, occurring only in women.

women.

FIG. 3.—Diagram of section through pyriform sinus of pharynx to show its relation externally to the thyroid cartilage and internally to the lateral wall of the larynx.

women, and are doubtless often an expression of "nervousness." It is perhaps for this reason that in a good many cases of post-cricoid carcinoma the early stages of definite dysphagia are not always taken very seriously. This is especially to be regretted, as the condition is a very formidable one, so that satisfactory treatment is more than usually dependent on early diagnosis. Symptoms that must always be regarded with very grave suspicion are definite obstructive dysphagia even if regurgitation is only occasional and slight, frequent choking fits during meals, and chronic laryngitis with huskiness from leakage of food into the larynx. Signs to be made out by examining the neck are all late and of little value; they are forward displacement of the larynx, palpability of the primary growth, and enlarged glands.

Laryngoscopic examination, if we know what to look for, is of great value in spite of the fact that by it a definite diagnosis cannot always be made. Three stages in the laryngoscopic appearances can usually be made out; examination, of course, is directed to the retroarytenoid region, and is quite easy. (a) In the earliest stages there is no growth visible and no swelling, but there is more or less chronic laryngitis, and in the pharynx behind the arytenoids is visible a pool of frothy mucus or muco-pus which the patient cannot clear away by swallowing. (Plate, Fig. 2.) (b) Later there is added to this picture a purplish, glistening swelling of oedema over the arytenoids and in the interarytenoid region. (Plate, Fig. 3.) (c) Finally, on the anterior wall of the pharynx below the top of the arytenoids there appears the raised edge of an epitheliomatous ulcer. Only quite a small segment of the ulcer may be visible, and it may emerge from the pool of mucus only momentarily and at the height of a strong effort of phonation. (Plate, Fig. 4.) Once such an appearance has been made out clearly the diagnosis is settled. The fixation of an arytenoid is common, but is usually a late phenomenon.

In the presence of strong reason to suspect post-cricoid carcinoma a characteristic laryngoscopic picture should not be waited for, but a direct examination should be made with the bronchoscope under an anaesthetic. On no account, however, should the surgeon be tempted to decide the vertical extent of the growth by forcing the tube past it. In my experience the operability of a given case of post-cricoid carcinoma can be decided definitely only by an actual exploration, though a negative decision can often be made by clinical examination in advanced cases. When an operation is begun in doubt as to whether it can be carried through, the operability of the case is to be judged without the pharynx being opened. In these circumstances retreat is possible without any serious damage having been inflicted.

TREATMENT.

There is one method of general utility in the operative treatment of carcinoma of the laryngo-pharynx. This is the operation of lateral (trans-thyroid) pharyngotomy, which is the foundation on which all the different procedures, from the simplest to the most elaborate, must be built up. It is primarily a method of access, and depends on the anatomical fact that the laryngo-pharynx lies within the laryngeal skeleton. If the great cornu of the hyoid bone and the ala of the thyroid cartilage are removed, the wall of this part of the pharynx is disclosed unopened, and through it the situation and extent of a growth can be determined by palpation with some precision. It can now be decided if a radical procedure is possible, and what it should be (Fig. 4). These are the essential facts, and I do not propose to enter here into technical details. We must consider, however, the further general lines on which we may be called upon to proceed.

The cases I have had to deal with in an experience of nearly twenty years' work in this field have fallen into three broadly distinguishable classes.

A. Inoperable Cases.—This class, always and still deplorably large, comprises probably a good half of all the cases I have had to do with. Most are recognizable for what they are at a glance; some have been, and a few still are, after every effort of foresight, submitted to fruitless exploratory operations. Here we have this satisfaction that the preliminaries that are necessary in such formidable cases are the best palliative measures that can be devised, and in themselves give great relief and some prolongation of life. These preliminaries are tracheotomy (in such circumstances under local anaesthesia) and a complete clearance of the mouth; they are measures always worth considering, even when there can be no thought of radical operation. There can be no doubt that a large proportion of the inoperable cases I have seen were at some part of their course favourable in type and within the reach of cure.

B. Operable Cases of the More Serious Types.—These are cases in which a more or less formidable operation offers a reasonable prospect of freedom from the disease for a period that may extend to several or many years. In order, however, that the life thus saved or prolonged shall be tolerable, it is necessary to deal with the mutilation the extensive operation has entailed by more or less complicated plastic procedures to restore the functions of respiration, speech, and deglutition. (Plate, Fig. 5.) It is impossible to describe here in detail any of the plastic measures that may be necessary, but we may indicate that some such procedure must invariably be foreseen in operations for post-cricoid growths, for growths on the posterior pharyngeal wall, and for growths of the epilaryngeal group when any large resection of the party wall between pharynx and larynx has been made. These cases, therefore, demand from the surgeon a certain amount of special experience, a readiness on his part to evolve the design and the carrying out of the operation together, and to improvise necessary modifications during its actual course. Of the cases that come to professedly radical operation probably about half belong to this class. They involve difficult and dangerous procedures, and have an apparently endless capacity for disappointing at any moment the most plausible hopes. Nevertheless, and perhaps especially for this reason, the small proportion of really complete success they provide is quite enough to encourage the effort to increase it. A special difficulty of this

FIG. 4.—To illustrate the principle of the operation of lateral trans-thyroid pharyngotomy. The outline of the laryngeal skeleton is shown. The finely dotted lines indicate the relative positions of the aryepiglottic fold, the arytenoid cartilage, and the vocal cord. The thickly dotted lines show where the great cornu and the thyroid ala are divided in the operation. When these parts have been removed the laryngo-pharynx is accessible.

group is that, as many of the cases are advanced, extensive gland dissections often must be done to obtain access to the primary growth. Such procedures are, in my experience, best combined in one operation, and it is often possible, by making use of the sterno-mastoid muscle as a partition in the wound, to preserve the raw area left by the gland dissection from infection from the pharynx and to secure primary union in it.

C. Operable Cases of the More Favourable Types.—This class includes as its most important members those growths of the epilaryngeal group that I have already mentioned as the most favourable—namely, those of the epiglottis, aryepiglottic fold, and lateral wall. These may amount to about half of all the operable cases. The epithelioma that occurs in the three sites mentioned is not of a very malignant form; even in the fairly advanced stages in which it is still so often first seen by the surgeon it is frequently not beyond cure; the situation is anatomically such that large excisions of the pharyngeal wall are possible without the need for plastic measures; the tendency to gland infection is not very strong, and is inclined to be limited to one side of the neck. For these reasons cases of this class can be approached by the surgeon with every reasonable confidence that decidedly satisfactory results will be obtained. There is probably none of the major types of malignant disease in general in which surgical treatment—with some allowance for the special local difficulties—is on the whole more satisfactory than it is in this far from uncommon group of epilaryngeal growths. This favourable estimate implies, of course, not

merely that there is a reasonable expectation of cure or prolonged freedom from the disease in all fairly early cases, but also that such results are to be obtained without the infliction of any serious mutilation or even disability. The tumour is to be dealt with by the operation of lateral pharyngotomy in its simplest form, and as in these circumstances it is reduced to a straightforward and almost formal procedure I shall venture to mention the chief points in the routine to the use of which, after innumerable variations, I have more or less definitively settled.

Lateral Pharyngotomy in the Early Epilaryngeal Case.

Preliminary Preparation.—As one confidently expects to be able to close the pharynx so that leakage into the neck cannot occur—if at all—for several days, I do not now insist on a preliminary clearance of the mouth in these cases. Thus the patient is saved a good deal of extra distress and about three weeks' delay.

Anæsthetic.—Chloroform first through the mouth, later through the tracheotomy tube, is always used. To keep down the total amount used—a most important point—cocaine solution (10 per cent.) is injected into the trachea before this is opened and applied to the interior of the pharynx in plugs as soon as the lumen is exposed. Small hypodermic injections of morphine (1/6 to 1/8 gr.), given during the operation, are also a help in reducing the dose of chloroform.

Tracheotomy.—This is always necessary. The immemorial procedure is modified in three important ways. The thyroid isthmus is never drawn aside, but if met with is freely incised or excised; the trachea is not merely incised but a disc one-third of an inch in diameter is taken out of its anterior wall. Thus the patient should be able to breathe freely through the tracheotomy wound before the tube is inserted. This is the only certain way of preventing dangerous emergencies or even fatalities when the tube is accidentally dislodged or deliberately changed. Finally, St. Clair Thomson's form of Durham's tube in its largest size is always used and is indispensable. The tube will be necessary for about a week; it is removed as soon as the patient can breathe easily through the larynx while the tube is stopped. It is a small and obvious point that the tube, when it is to be discarded, should be taken out in the morning. Healing of a tracheotomy wound is usually quicker when a disc has been removed than when the trachea has been incised, for there is much less likely to be necrosis of the rings.

Gland Operation.—Only unilateral gland infection has to be provided against. When glands are palpably involved the usual complete unilateral dissection is done with removal of the jugular vein and ligature and division of the external carotid close to the bifurcation, but with preservation of the sterno-mastoid. The anterior edge of this muscle is then stitched to the prevertebral fascia behind the pharynx and the gland wound behind it drained by a separate puncture. If the glands are not obviously involved a rather limited gland dissection is done in the anterior triangle and the sterno-mastoid stitched over the vessels as mentioned above.

The Pharyngotomy.—A vertical incision is made over the middle of the lateral aspect of the larynx down to the cartilages and the infrahyoid muscles and constrictors are

turned forwards and backwards so that the great cornu of the hyoid and the thyroid ala are completely exposed. The structures on the deep surfaces of these are separated from them with a raspator, and then the great cornu is removed to its joint, as well as the posterior two-thirds or more of the ala. The lax pharyngeal wall is now exposed, and the situation and extent of the growth are easily made out through it. The wound is carefully protected from the contact of pharyngeal mucus, and the pharynx is incised in such a way that this incision will serve in part for the isolation of the tumour. The removal of the latter with an adequate margin is then completed. The gap left is carefully closed by stitches, and in the same procedure the incision in the pharyngeal wall is stitched up. The constrictors and infrahyoid muscles are brought together closely over the line of suture in the pharynx. The neck wound is left widely open. It is filled with sterile boric powder and plugged over an apron of green protective. It should be the object and expectation of the surgeon to avoid altogether infection of the neck wound from the pharynx, both during the operation and after. A small rubber catheter is left in the pharynx and brought out through the mouth for feeding. It is left in for about five days and then passed for individual feeds.

In about a month healing should be complete, swallowing normal, and speech rapidly recovering its usual strength. This estimate applies only to favourable cases; there are, of course, many variations in the length of convalescence, and the patient may need skilled nursing and surgical care for some weeks more.

SOME FINAL CONSIDERATIONS.

When we turn to consider in general the results of the surgery of malignant disease of the laryngo-pharynx, it is but fair to remind ourselves in the first place of what the results of the disease are without sur-

gery. There is no more dreadful form of malignant disease, and we are to remember that the favourable easy types left untreated are spared nothing in the end. Again, we may well remind ourselves that the treatment we can use is no surgery of mutilation, but looks to leave the patient capable of leading a normal unmarked life. Such considerations may allow us to regard with a certain indulgence the large gaps between what we should like to do and what we can do in this department.

At the present time two conclusions seem to me to be fairly definite. In the first place we have technical methods which seem soundly established and capable of progressive refinement and extension. In the second place we can say that, in cases carefully but not very rigorously selected as favourable, we can look for satisfactory results as to the disease, secured by drastic but not very dangerous operations which leave no serious disability.

One of the accompaniments of progress in the surgery of any kind of malignant disease seems always to have been the disclosure of the extent to which late recurrences are possible. In my experience the surgery of the pharynx has followed this rule. I have, for example, comparatively recently seen two cases in which after seven years of complete freedom there has been a return or fresh outbreak of the disease. To my mind such events are not wholly discouraging, for they show how our efforts are helped by the natural resistive powers of the body, and even to put the case on the humblest level, health for seven years is no inconsiderable gift.

DESCRIPTION OF COLOURED PLATE.

FIG. 1.—Epithelioma of lateral wall: redrawn from a sketch of the At first sight the growth seemed to have and the case appeared to be unfavourable, however, freely movable, and this suggested act have begun on the lateral wall. At the case, and a satisfactory local excision to the arytenoid. The case illustrates the to growths of the lateral wall by their

FIGS. 2, 3, AND 4.—Laryngoscopic appearances of post-cricoid carcinoma. These drawings are not intended to reproduce individual cases but to give a generalized idea of the three stages referred to in the text. In Fig. 2 the only abnormality is the pool of frothy mucus behind the arytenoids that indicates obstruction of the hypopharynx. In Fig. 3 oedema of the arytenoid region has appeared. In Fig. 4 the upper edge of an epitheliomatous ulcer is visible. In strong phonation this would show more extensively.

FIG. 5.—To illustrate the type of plastic procedure necessary in connexion with the more extensive operations. Drawing made some weeks after primary operation for a large growth. The excision involved removal of a large part of the pharynx and larynx, and, of course, of the party wall between them. Repair of the defect has been prepared for by the implantation of a large folded flap of skin presenting epithelial surfaces to the pharynx and larynx. At the second operation this flap will be used to re-form the upper laryngeal opening and the wall between larynx and pharynx, and the wound will be completely closed.

A Lecture ON THE DEVELOPMENT OF VAGINAL OPERATIONS FOR GENITAL PROLAPSE.

GIVEN TO GRADUATES AT ST. MARY'S HOSPITAL, MANCHESTER,

BY
W. E. FOTHERGILL, M.A., B.Sc., M.D.,
PROFESSOR OF CLINICAL OBSTETRICS AND GYNAECOLOGY, VICTORIA
UNIVERSITY, MANCHESTER.

VAGINAL surgery is now uniformly successful in cases of genital prolapse, and recurrence is rare, even when pregnancy and labour follow and severely test the efficiency of the treatment. What exactly is meant by the term "genital prolapse"? Judging from the published writings, the private correspondence, and the conversation of medical men, it includes four conditions, which occur alone or in combination.

CLASSIFICATION OF CASES.

1. *Cystocele*, in which the anterior vaginal wall with the urethra and part of the bladder bulges in the vulvar cleft, the uterus remaining in its usual position.
2. *True prolapse*, in which the anterior vaginal wall, urethra, and bladder descend first, followed next by the cervix, and last by the posterior vaginal wall.
3. *Long cervix with loose uterus*, in which the cervix emerges first at the vaginal orifice, followed by the vaginal walls, inverted from above downwards, round the descending uterus.
4. *Rectocele*, in which the posterior vaginal wall and the anterior rectal wall descend together and bulge in the vulvar cleft.

The three combinations are (a) rectocele and cystocele; (b) rectocele and true prolapse; and (c) rectocele and long cervix. Nearly all the cases that are sent to hospital as examples of genital prolapse fall into one or other of these seven categories—four conditions and three combinations of them. It may be taken for granted that in nearly all these cases the perineum is defective, and has either been torn or has been stretched by the descending structures. The operations used are combinations of anterior colporrhaphy and amputation of the cervix; followed by perineorrhaphy unless there is rectocele, when colpo-perineorrhaphy is done. Our present object is to trace the origin and development of these operations. We must remember that the great majority of methods and technical devices have blossomed for a time, only to fade away into the limbo of oblivion. They have been divergences from the direct line of evolution. Our predecessors and we ourselves have proved all things and have held fast, for the most part, only that which is good. Thus we can omit reference to the greater part of the work that has been done and most of what has been written, because they have led nowhere, and their main use has been to show how things should not be done.

ANTERIOR COLPORRHAPHY.

Marshall Hall¹ of London thought out an operation for prolapse which was done for him by a surgeon named Hemming in the year 1831. A large portion of the anterior vaginal wall was cut away, making a wound one and a half inches wide extending between the cervix and the vaginal outlet. The first suture was put in at the cervical end of the wound, the next below it, and so on. Thus the prolapsed organs went up into the pelvis as the wound was closed from side to side. This was very like a modern anterior colporrhaphy, and an independent observer reported a couple of years later that the patient was cured. But the operation was lost for a time, as Hemming's followers seem to have been afraid of injuring the bladder. They made their wounds lateral instead of anterior, and some were content to "scarify" or "denude" the surface instead of removing the whole thickness of the vaginal wall. In 1844 Kilian made a wound which was anterior and triangular, with its base towards the cervix. In 1866 Marion Sims² excised an oval portion of the vaginal wall, cutting through its whole thickness. But it is not clear

that he continued to do this, and both Sims and Emmet modified the operation without improving it. Savage in 1858, Aveling in 1866, and Morton in 1869 seem to have used rather half-hearted methods. But Gaillard Thomas³ certainly realized the importance of cutting through the whole thickness of the vaginal wall, for about the year 1872 he began separating it from the bladder by means of an instrument like a glove-stretcher introduced through a small incision. From this time onwards anterior colporrhaphy was a recognized operation mentioned in most books.

AMPUTATION OF THE CERVIX.

Removal of the cervix for genital prolapse was performed by Huguier⁴ in 1848. He did a high operation, using the scalpel, though he is said to have condescended to the écraseur in some of his later cases. Goupi⁵ removed a smaller portion of the cervix by means of the écraseur. In 1856 Sims² was amputating the cervix in some of his cases, and he much improved technique by closing the wound with sutures instead of leaving it to granulate. The well known method associated with the name of Schroeder subsequently came into general use, and innumerable modifications have been described.

PERINEORRHAPHY AND COLPO-PERINEORRHAPHY.

The distress of women who had been torn right through the rectum must have called for surgical treatment from a very early date. The operation was successful in the hands of Guillemeau, a pupil of Paré, and from his day onwards cases were recorded from time to time. Dieffenbach⁶ published his work in Berlin in 1829, and Roux followed in Paris in 1834. The name of Baker Brown may be mentioned, as he read a paper on the subject in London in 1851. From that time on perineorrhaphy for complete tears has been improved by surgeons too numerous for citation.

Perineal operations for prolapse also had another origin, for in certain communities it was usual to protect the virginity of the unmarried girls by rawing the inner surfaces of the labia majora so that, as healing occurred, they united in the middle line. Thus a barrier was placed across the vulva which was ultimately divided as a part of the ceremony of marriage.

This idea was taken up by Fricke⁷ in Germany in 1832, and by uniting the labia majora he bridged the vulva with the object of supporting the prolapsed uterus. This operation on the vulva was called episiorrhaphy, and it had a very considerable vogue. But from the labia majora the surgeons gradually worked back to the perineum and up into the vagina; and they dropped episiorrhaphy as they developed perineorrhaphy and posterior colporrhaphy. Simon's⁸ "kolporrhaphia posterior" was done in 1867, and Emmet⁹ was removing an oval portion of the posterior vaginal wall at one sitting and repairing the perineum at another; but by 1880 he had begun to combine the two operations in one—colpo-perineorrhaphy.

Between 1874 and 1881 Hegar¹⁰ modified the operation until it closely approached its modern form. He removed a triangle of posterior vaginal wall whose apex was near the cervix in the posterior vaginal fornix, while its base curved along the margin of the perineum. He worked from above downwards, sometimes in stages, traction being aided by the use of the knife. The wound was closed by a combination of deep and superficial sutures. Bischoff of Basle, Martin of Berlin, Pozzi of Paris, and many others modified this operation. The common error seems to have been the belief that it would cure uterine prolapse. Garrigues was one of the first to recognize that its use is for rectocele.

RESULTS.

There are many indications that for a long time the ultimate results of vaginal surgery for prolapse were not brilliant. Some writers definitely say so. Walter Whitehead¹¹ of Manchester, for example, wrote a good paper in 1871. He was aware of the distinction between true prolapse and long cervix. He recorded fifteen cases which he had treated, using anterior and posterior colporrhaphy and amputation of the cervix; but he expressed himself as very far from pleased at the results. Routh was using

similar operations, and Emmet's work in 1880 was of the same character. But no one gave definite teaching as to how to cure prolapse. The multitudes of variations and modifications that were introduced show that in general results were not good. Indeed, the opinion that up to 1899 there was no satisfactory surgical treatment for prolapse is upheld by Dr. R. H. Paramore.¹² There is no more thorough student of the literature of prolapse than this author, whom I thank for much information and many references. Another indication of the partial failure of vaginal operations is the great popularity which was gained, in spite of their inefficiency, by various abdominal suspension operations.

But, though the results of plastic vaginal surgery were not uniformly good, still most surgeons could say that many of their cases were successful, and certain operators secured permanent cure in nearly every case. Donald,¹³ for example, began operating in Manchester in 1888, and has always been so successful with a wide anterior colporrhaphy, amputation of the cervix, and a very efficient posterior colporrhaphy, that he has never thought it desirable to use any abdominal suspension or other method. My own personal experience dates from 1895, and the results were good from the first. But when amputation of the cervix was omitted recurrence was occasionally noted, and some cases failed to stand the test of pregnancy and labour. I have never used suspension or other methods, nor have I seen them employed in the Manchester Royal Infirmary or St. Mary's Hospital.

RATIONALE OF VAGINAL OPERATIONS.

Why did plastic vaginal operations succeed in some hands and in some cases while they still failed to satisfy the majority of surgeons? The objects of narrowing the vagina, shortening the uterus, and restoring the integrity of the perineum were generally attained. Why did the prolapse so frequently recur? Such questions disturbed our minds for long, and they were only answered in the light of new information gained by surgical experience and anatomical research as to the normal supports of the pelvic viscera. The rationale of prolapse and its treatment was only explained when it was realized that the uterus, vagina, and bladder are not so much suspended from above or propped up from below as they are attached by their sides, where they receive their blood supply, and held in their normal position by the subperitoneal tissue which intervenes between the organs and the more fixed lateral structures in the pelvic floor. This had been described by various anatomists, including Elliot Smith, Cameron, and Derry, when I¹⁴ brought the subject before the Royal Society of Medicine in 1907; but some little time elapsed before this teaching was generally accepted. But with this information we can see how vaginal operations work, for the removal of a wide portion of the vaginal wall exposes the lateral tissue or paracolpos. When the wound is sutured, unstriated muscle and connective tissue that formerly lay far apart at the sides of the vagina are brought together in the mid-plane of the pelvis. This lengthens the course of the structures and so tightens them up, thus restoring efficiency to the attachments of the vagina and bladder. Again, high amputation of the cervix exposes the parametrium and allows its right and left portions to be brought together in the middle line in front of the stump of the cervix. In other words, anterior colporrhaphy works not so much by narrowing the vagina as by exposing the paracolpos; and amputation of the cervix works not so much by shortening the uterus as by freely exposing the parametrium. In this light it is clear that those of us who gained success when these operations were still empirical must have operated in such a manner as to secure good union of lateral tissues in the mid-plane of the pelvis.

Consequent Changes in Technique.

How could these operations be simplified and standardized so as to place uniform success within the grasp of any competent surgeon? At the Edinburgh Obstetrical Society in 1907¹⁵ I advocated the extension of the anterior colporrhaphy wound far into the lateral fornices with the object of securing better exposure of the paracolpos than is given by the ordinary colporrhaphy wound, together with

exposure of the under surface of the parametrium. This modification was followed by improvement in my own results; but I soon realized the importance of high amputation of the cervix to secure efficient exposure of the parametrium. In 1910 I saw the way to a great simplification, and began to excise a large portion of the anterior vaginal wall together with the cervix in one piece. The incision begins half an inch above the urethral orifice, passes wide of the cervix on either side, and ends behind it. This leaves a quadrilateral wound narrow below, wide above, with the stump of the cervix near its posterior angle. The bladder, freely separated from the cervix, is well out of the way. The parametrium is much better exposed than is the case when the amputation and the colporrhaphy are done one after the other. Beginning in the mid-line behind, the vaginal wall is sutured to the cut edge of the cervical canal until the stump of the cervix is surrounded and covered in. The rest of the wound is closed from side to side by interrupted sutures which take a good bite of the paracolpos together with the edge of the vaginal wall. As this is done the cervix passes upwards and backwards, and the uterus is left in antversion. This combination of anterior colporrhaphy and amputation of the cervix in a single operation was published in 1913¹⁶ and in 1915. It has proved during the last fifteen years to be simple, safe, and efficient.¹⁷ It is generally followed by perineorrhaphy, colpo-perineorrhaphy being used whenever rectocele is present. Dr. Lacey's¹⁸ inquiry into ultimate results was published after the Birmingham congress had discussed them in 1921. He found that 97 per cent. of my cases in 1914-15-16 were permanently cured. Thirty children had been born to twenty-four of the patients. One of them who had had three children required further operative treatment; this patient's cervix was not removed at the first operation, or the result might have been better.

THE OPERATIVE TREATMENT OF HERNIA IN INFANTS AND YOUNG CHILDREN.*

BY

ANDREW FULLERTON, C.B., C.M.G., M.Ch.,

F.R.C.S.IREL., HON. F.A.C.S.,

PROFESSOR OF SURGERY, QUEEN'S UNIVERSITY, BELFAST; VICE-PRESIDENT, ROYAL COLLEGE OF SURGEONS, IRELAND.

THE remarks which follow deal with a consecutive series of operations for inguinal hernia in infants and young children. Most of these were performed in the out-patient department of the Belfast Hospital for Sick Children, and a comparison is made of the results of these operations and those performed in the wards and in private practice during the same period.

When the British Medical Association held its Annual Meeting in Belfast in 1909 the late Mr. J. H. Nicoll of Glasgow advocated the treatment of hernia in children by operation in the out-patient department. The late Mr. Robert Campbell of Belfast, who was at that time a recognized authority on the surgical affections of children,

*Read at a meeting of the Ulster Branch of the British Medical Association, January 21st, 1926.

and especially interested in hernia, had already done pioneer work in this direction, and had advocated early operation in an address read before the Ulster Medical Society in 1903. Mr. Campbell, about the time of the meeting referred to, had begun to perform these operations in the out-patient department, and had so infected his colleagues with his enthusiasm that it soon became the established custom in Belfast. This gave rise at first to some criticism among the governors of the Children's Hospital, but all objections were finally overcome, and a well equipped out-patient theatre was soon provided for these and similar operations by an enlightened and appreciative board of management. I have in my possession a paper in manuscript written by Mr. Campbell and duly presented at a meeting of the Ulster Medical Society during the session 1905-6, in which he gives an account of 305 operations for the radical cure of hernia in children, with no deaths and only two cases of suppuration. Mr. Campbell's subsequent records have not been published, but I understand that the total of these operations reached something in the neighbourhood of 1,500, with only one death.

My own earlier work in this direction began about the year 1909 and was carried on for many years entirely in the out-patient department without a single death. Notes suitable for statistical purposes, however, were taken in the last 300 cases only, and include those operated on in the wards and in private practice, as well as those operated on in the out-patient department. The present article, then, concerns a consecutive series of 300 children in which the radical cure of inguinal hernia was carried out. The notes, which are very brief, record the age and sex of the patient, the side affected, the general characters of the hernial sac, its contents, if any, and whether or not it communicated with the tunica vaginalis testis, together with any other items of special interest. The total number of separate operations was 326.

Sex.—There was a large preponderance of boys (265 males to 35 females).

Side Affected.—The hernia was confined to the right side in 186 cases, to the left in 78, and was present on both sides in 36.

Characters of the Sac.—The sac varied in type from a pear-shaped, flat, opaque structure, with a well defined rounded lower border lying high up in the cord, and difficult to imagine as ever having had any connexion with the tunica vaginalis, to a thin membrane, often of great tenuity, descending to the scrotum, where it was closely applied to, but not firmly adherent to, the tunica vaginalis, and from which it could be separated by gauze dissection, assisted, perhaps, by a few touches of the knife. (See Figs. 2, 3, and 4.) In some of the cases little white polypoid projections were found on the inner surface of the sac near the neck, and various thickenings were occasionally found in the walls, the nature of which was not determined.

Relation of the Sac to the Tunica Vaginalis Testis.—Counting a double hernia as two, 298 male hernial sacs were investigated, and in 22 only was there a communication with the tunica vaginalis testis—that is, in a little over 7 per cent. In three of the cases of double hernia the sac was continuous with the tunica vaginalis on one side, and in each case the right. In a fourth case the sac was continuous with the tunica vaginalis on both sides.

There does not seem to be much point in retaining the term "infantile" as applied to inguinal hernia. The

varieties of infantile hernia, as described in textbooks, depend on the presence of a large tunica vaginalis and the various ways in which it may be invaginated by the descent of a hernia. More important, from an anatomical point of view, is whether or not the hernial sac is continuous with the tunica vaginalis testis.

It might be instructive to digress for a moment to consider what is known as encysted hydrocele of the cord. This condition is, I believe, nothing more or less than a pear-shaped hernial sac that has become obliterated at its upper end and whose fundus has become distended with fluid. (See Figs. 2b, 3c, and 4d.) If these cases are carefully dissected, it will be found that the lower end is rounded and quite easily separated from the surrounding structures. I have not seen an encysted hydrocele of the cord that could be said to resemble a dilatation of the central part of an otherwise obliterated tube reaching from the internal ring to the tunica vaginalis. The upper end terminates in a band or cord which looks like the neck of a hernial sac, and the lower border is always well defined and shows no prolongation resembling the remains of an obliterated tube. Further, in a certain proportion of cases this sac descends as far as the testis and invests the tunica vaginalis, giving rise to a condition closely resembling an ordinary hydrocele. (See Fig. 4d.) In such cases, by

careful dissection the sac may be separated from the tunica vaginalis, leaving the latter intact. An encysted hydrocele may be present on one side and a hernia on the other. The sacs are similar, except that one contains fluid while the other contains abdominal contents.

Strangulation.—There were two cases of strangulation in this series. One of these occurred in a boy, aged 6 weeks. He had been vomiting for a week, finally bringing up foul-smelling stuff. The sac contained small intestine, which was dark in colour, but viable. After carefully freeing the neck of the sac it was possible

to reduce the bowel without incising the hernial ring.

Contents of the Sac.—Only very rarely was operation undertaken while the hernia was "down." The invariable practice was to reduce the hernia, if possible, and keep it reduced, thus avoiding one of the most annoying accidents that may happen. If a hernia comes down and escapes through a rent in the sac during the operation the difficulties of the latter are much increased, especially if the child is straining. The opening in the abdominal wall is very small, and, the guide into it being torn, it may be impossible to return the prolapsed bowel. In one case in which the appendix and caecum were adherent to the sac I found, after separating the adhesions, that it was impossible, without damaging the bowel or slitting up the hernial ring, to effect reduction. The difficulty was got over by opening the abdomen through a McBurney's incision and gently drawing the caecum through the hernial opening from within. The appendix was removed, and the operation completed in the usual way. I have seen the appendix alone in the sac, and have found no difficulty in removing it as it lay, pulling it down just sufficiently to enable the stump to be satisfactorily dealt with. In a few cases omentum was found, and in one adhesions had to be divided before reduction could be effected. The Fallopian tube was present in several cases, and in one or two the ovary presented. The most usual viscus, however, was the small intestine.

In two cases a small diverticulum of the bladder was found adherent to the sac and might easily have been tied off with it. Fortunately the condition was recognized and

FIG. 1.—Unusual form of congenital hernial sac, communicating with tunica vaginalis testis (7 per cent. of cases in present series).

FIG. 1a.—Congenital hydrocele in which the hernial sac may become obliterated at its upper end, and distended with fluid.

FIGS. 2, 3, AND 4.—Various degrees of extent of the usual type of hernial sac (93 per cent. of cases in present series).

FIGS. 2b, 3c, AND 4d.—Showing how a hernial sac may become obliterated at its neck, and distended with fluid to form an "encysted hydrocele of the cord."

FIGS. 5a AND 5b show two types of "infantile" hernia.

the bladder wall was not included in the ligature. In addition to these there were a few cases in which, on pulling down the sac so as to make sure of ligaturing the neck high up the bladder was dragged upon. The muscular wall of the latter was recognized and carefully separated from the sac before the ligature was applied.

The Operation Performed.

The operation carried out in these children is of the simplest type. An incision about an inch long is made over the upper end of the sac, the cord is isolated, and the index finger of the left hand is passed under it so as to spread out the component parts. With light touches of a sharp knife the successive coverings are divided longitudinally and reflected till the sac is reached. The latter can then be separated by blunt dissection with gauze and forceps until the neck is freed as high up as possible, taking great care to avoid injury to the delicate vas. The neck of the sac is then transfixed with a small round needle, tied off with fine catgut, and allowed to retract. In some of the earlier cases the sac was invaginated and brought out through a separate opening in the external oblique, fixed to the aponeurosis, and the projecting portion cut off, but this method was soon abandoned in favour of the more simple procedure. In female children it is impossible in most cases to separate the round ligament from the sac, and this structure is therefore included in the ligature occluding the neck of the sac. In all cases, male and female, it is a wise precaution, just before ligaturing the neck, to open the sac, so as to exclude the possibility of the presence of abdominal contents. The inguinal canal is not interfered with in any way, and only in a very few cases of this series were sutures placed in the pillars of the external ring. After tying any bleeding vessels—and it is surprising how seldom it is necessary to ligature a single branch—the skin wound is closed with a subcuticular silkworm-gut suture, the ends of which are tied over a pad of gauze, which is left in position until the wound is quite dry. The suture is then cut about an eighth of an inch from the point where it enters the skin at either end of the wound, and a collodion dressing applied. At the end of a week the dressing is stripped off and one end of the suture is grasped with forceps and pulled upon so as to remove the stitch. Another collodion dressing may then be applied, but, as a rule, all that is necessary is a little dusting powder. Cases operated on in the out-patient department are taken home as soon as they have recovered from the anaesthetic, and are brought back for inspection in two or three days' time, when further instructions as to attendance are given.

The operation may take a few minutes only to perform, but, if the sac is very thin and extends down towards the tunica vaginalis, careful dissection requires a somewhat longer time. The test of clean, accurate work is the absence of swelling of the testicle on the affected side after the lapse of a few days. Much handling of the cord invariably leads to swelling of the testicle, which may take ten days or longer to subside.

Preparation of the Patient.—In the out-patient department a leaflet is given to the mother or other responsible person, containing directions as to an aperient, bathing of the patient on the morning of the operation, and feeding, but these instructions are frequently neglected, and a dirty child who vomits solid food and defaecates on the operation table is often the result. The preparation of the skin by soap and water, ether, and an antiseptic (mercury biniodide, iodine, or picric acid in spirit) is carried out while the child is being anaesthetized. In the early days the operation was often performed without the services of an assistant. Without elaborate preparations and with the simplest technique the results have amply justified early operation, and particularly the surgery of the out-patient department.

Anaesthetic.—As to the anaesthetic, we used in the early days to give chloroform, but this has now been abandoned in favour of open or warm ether. More elaborate preparations are carried out in the wards, where the child is given glucose for several days, and a small dose of atropine just before operation.

While in the out-patient department I had hand-towels

made with a slit, about three inches in length, in the centre. One of these diminutive abdominal towels is clipped to the skin so that the slit exposes the operation area. This effects a considerable saving in towels; and has proved quite satisfactory.

Statistics.

I have notes of 184 children operated on for inguinal hernia in the out-patient department. The total number of operations was 209. This is accounted for by the fact that 32 of the patients had a double hernia, and in only 7 of these were both sides dealt with at the same time. In 25 patients, therefore, two separate operations, with an interval of several weeks between them, were carried out, as this was considered safer in out-patient work. The ages of these children were as follows:

Under 3 months	77
Between 3 months and 1 year	48
Between 1 and 2 years	31
Between 2 and 12 years	28

Some degree of sepsis took place in 5 cases—that is, just under 2.4 per cent. Sepsis was understood to mean anything from a stitch abscess to opening up of the wound. There were no deaths, though in one case, a child 1 month old, tracheotomy was performed for laryngeal spasm. One case was a strangulated hernia. Most of the others were reducible.

The private cases and those treated in the wards number 116. Four had double herniae, and of these 3 had both sides dealt with at the same operation. This gives a total of 117 separate operations. The ages of the children were as follows:

Under 3 months	7
Between 3 months and 1 year	18
Between 1 and 2 years	14
Between 2 and 12 years	77

Some degree of sepsis occurred in 3 cases—that is, just under 2.6 per cent. There were no deaths.

It will be seen that most of the very young children were operated on in the out-patient department—125 under 1 year, as compared with 36 in the wards and in private practice. Young children are easily carried to and fro, and are better with their mothers. These two series taken together give a grand total of 326 separate operations, with 8 cases showing some degree of sepsis (2.4 per cent.) and no deaths. There were 3 cases of recurrence, of which one was in a child operated on in the out-patient department.

These statistics prove conclusively that operations for hernia in infants and young children are as safely conducted in the out-patient department as in the wards; in fact, from the figures quoted, the balance, if anything, is slightly in favour of the out-patient department.

Two great advantages are gained by operating in the out-patient department:

1. The child, if being nursed by its mother, does not suffer the inconvenience and risk of being weaned. It would be impossible in this district to have the mother in the vicinity so as to be able to attend at the hospital at stated times to nurse her child.

2. The range of usefulness of the hospital is enormously increased, the beds which would otherwise be occupied by cases of hernia being available for other patients. This is a great advantage in a small children's hospital like ours.

Conclusion.

I hope that the effect of this contribution will not be to leave the impression that the operation of herniotomy in a child should be considered a trivial affair, devoid of difficulty and danger. Nothing could be further from the truth. The more experienced the surgeon, the more he realizes that the difficulties may be very great indeed, especially with a very thin sac in a straining child. One sees occasionally, alas! a sac torn to shreds and a vas irreparably damaged by clumsy surgery. The operation is, indeed, one that demands careful and delicate manipulation, each structure being recognized as it is exposed. Given these conditions, there is no more satisfactory operation in the whole range of surgery.

I am indebted to Dr. R. H. Hunter for the accompanying drawings.

CONSTIPATION AND ITS MANAGEMENT IN INFANCY AND CHILDHOOD.*

BY

DONALD PATERSON, B.A., M.B., M.R.C.P.,

PHYSICIAN FOR THE DISEASES OF CHILDREN, WESTMINSTER HOSPITAL;
PHYSICIAN TO OUT-PATIENTS, HOSPITAL FOR SICK CHILDREN,
GREAT ORMOND STREET.

We must ask ourselves first, What are the common causes of constipation in infancy and childhood? I would enumerate them as:

1. An inability on the part of the mother or nurse to establish a regular habit of evacuation of the bowel.
2. Atonicity of the bowel as part of a general debility most commonly found in the "chronic dyspeptic" or "nervous exhaustion" child.
3. Fear of the act of defaecation because of anal fissure.
4. Insufficient or wrong food.
5. Interference with the passage of the intestinal contents due to stoppage in the alimentary tract.
6. Faulty reaction of the older child of school age to school regime.

By far the commonest cause is the inability of the mother or nurse to establish regular bowel habits. To be entirely successful the proper training of the child should commence almost from birth. The infant should be placed on a soap-dish or held out several times daily so that a firm association is established between both the feel of the vessel and the attitude with the movement of the bowels. This simple fact is universally acknowledged and practised with success by the good nursery nurse or mother. Only a proportion of the population, however, are able to maintain the care of the infant with the machine-like regularity necessary for its success. Some small domestic upset prevents the morning or evening care, and the habit acquired by weeks of patience is quickly lost. The busy, ignorant, or careless mother, who waits until the napkin is soiled and then changes it, as though she had performed her whole duty towards the child, is indeed far wrong. Were she to sacrifice more time to establishing the reflex habit she would save herself much of the tiresome duty of cleansing napkins. In addition, bouts of diarrhoea and constipation would become increasingly rare and purges unnecessary.

In the management of the older child so much depends on how he has been trained in his infancy. If, in the first place, proper habits have been established, he knows nothing else, and approaches the vessel filled with self-confidence in his ability to empty the bowel. If, however, his infancy has been filled with periods when he was constipated or had diarrhoea with much purging and utter failure on many occasions to get the bowels to move, the vessel is approached in a timid fashion. The child doubts his ability to perform the act, and, in fact, has failed before it has been attempted.

To correct this is no easy matter. The child should be placed on the vessel twice daily, always at the same time. It should be made quite plain to him by those in charge what he is placed there for, and he should not be allowed to get up until it is apparent that he has made a real effort. The attitude of the mother or nurse towards him is of vital importance. His failures should not assume undue importance—in fact, no apparent notice should be taken of them, and he should on no account be allowed to see that his failure upsets anyone. On the other hand, his successes should always be praised extravagantly. Encouragement and optimism should invade the nursery especially at this time, so as to establish the child's self-confidence.

There is a type of child, very commonly seen both in private practice and in the out-patient department of hospitals, who might be termed the "chronic dyspeptic." The tongue is always dirty, gastric upsets are common, constipation is obstinate. Inquiry into the life of this child elicits these facts: He is up early in the morning, and is on the go, never resting throughout the day. He is bright and forward, and his company is sought after, with the result that his bedtime is later than the average child. He is over-tired, and sleeps unduly soundly. This

child takes life too seriously. He has no time to eat his meals properly, but rushes off to accomplish the maximum. His stomach, filled at breakfast, fails to empty before dinner, and the food taken at dinner is often present in his stomach at tea-time. In later life he becomes the chronic dyspeptic of the nervous type or the neurasthenic. There is no wonder that, leading this hurried life, little attention is given to emptying the bowel. Physically this child is thin, nervous, under weight, and easily tires, and may be termed the "nervous exhaustion" child.

To treat such a case the whole child and his environment must be carefully considered. The entire regime of his life must be altered. His day must be shortened, rest encouraged, his overanxiety towards his work checked. His meals must be served with machine-like regularity and punctuality, and a complete rest or relaxation secured after each. Thus the pylorus will open and the food is allowed to pass on. Often this is only made possible by sending him away for a complete change to other surroundings. A mixture containing 3 or 4 grains of powdered rhubarb and 10 grains of sodium bicarbonate given at bedtime and first thing in the morning over a period will be found most useful to clean the tongue and improve the child's bowel habits. I would add, however, that to concentrate on the constipation to the exclusion of the general condition of the child is merely to court failure.

It is not uncommon to be told that an older infant or toddler screams whenever placed on the vessel, and that it is only by means of purges that the bowels can be made to move. To the observant mother or nurse it is clear that the vessel is associated in the child's mind with pain. In an effort to pass a formed constipated motion there has been a tear in the anal mucous membrane, and the observant nurse will have noted a smear of bright blood adhering to the surface of the stool. At each subsequent defaecation there is pain, and the anal sphincter may be in a state of spasm as a result. The child's confidence in his ability to pass a motion without pain must be restored as quickly as possible. Some liquid paraffin preparation should be given so that the motion is kept quite soft. A preparation of the galls and opium ointment (B.P.), diluted with an equal part of vaseline, should be smeared about the anus, and a little actually passed into it, both before and after passing the motion. Rapid healing then, as a rule, takes place.

Insufficient or wrong food may be a cause of constipation. Often in the breast-fed infant the first symptoms that the milk is failing is that weight is not gained and that there is obstinate constipation. In warm weather, when the child is perspiring, this may merely mean that more fluid is required, and drinks of water will quickly set this right.

The protein or curd of milk produces an alkaline stool. The fat or cream splits down into fatty acids, which produce an acid stool. In excess these acids may excoriate the bowel, causing diarrhoea. In smaller quantities they form soaps, producing a dry, pale, crumbly stool. The sugars or starches of the diet ferment into acids as well. The proportion of protein in breast-milk is small in relation to the sugar, with the result that the breast-fed infant's stool is acid. The artificially fed baby, on the other hand, tends to be slightly constipated, as judged by breast-fed standards, and to pass an alkaline stool. It is thus seen that a nice balance must be attained between the constipating alkaline protein and the diarrhoea-producing fat and sugar. It can be readily seen that a slight increase in the sugar content of the artificial feed will tend to correct a minor degree of constipation. On the other hand, a too creamy mixture first produces the pale, crumbly, constipated soap stool, later to give rise to the thin, acid, offensive diarrhoeal stool. In the older child this same nice balance must be maintained, but in addition the food should be such that it cannot be absorbed completely. Coarse foods must be given which will form a residue, stimulating the bowels to peristaltic action. Rusks, crisp toast, or coarse brown bread (instead of white bread-and-butter), and green vegetables containing plenty of cellulose should be insisted upon. Fruit, raw or cooked, should be given with at least one meal each day. A little molasses, honey, or malt, by its tendency to fermentation, aids peristalsis.

* A lecture given at the Hospital for Sick Children, Great Ormond Street.

Newborn infants may suffer from some form of congenital stenosis or atresia of the alimentary tract, with consequent constipation. The commonest of these is congenital pyloric stenosis, in which the constipation is a cardinal symptom of the condition. Congenital duodenal stenosis or atresia is a much rarer condition. Stenosis of the rectum or sigmoid portion of the bowel, known as Hirschsprung's disease, is also uncommon. In the two former conditions operative intervention is demanded, but in the latter the careful dieting and management of the child yields excellent results.

Some children who have reached the school age and acquired the utmost regularity of bowel movement then seem to develop obstinate constipation. This is much rarer in the school boy than in the school girl. Sometimes these irregular habits may be traced to the child neglecting the opportunity she is given to empty the bowel. Occasionally it is because there is no opportunity given at school—either there is no time allotted for such purpose or there is insufficient lavatory accommodation. She misses the maternal care and urge to good bowel habits. Such cases can only be set right by the school authorities themselves.

Medicinal Treatment.

Beyond a very few preparations, and on few occasions, no drugs or medicines should have to be used. If they do have to be given it should be for a short time only. The following will be found to aid the regaining of good habits. In the infant one of the liquid paraffin preparations, such as plain liquid paraffin or senprolin emulsion, Angier's emulsion, petrolagar, or virolax, may be given in teaspoon doses night and morning. In older infants, if this is not enough, and especially during the teething period, an occasional grey powder given at bedtime (one grain at 6 months, two grains at 18 months, and three grains at 3 years); in the morning one or two teaspoonfuls of milk of magnesia should be given. For those elder children, in whom liquid paraffin will not control constipation, the rhubarb and soda mixture will be found a great help.

To take a long or general view of constipation in children is the only view which, in my opinion, leads to success.

A HISTORICAL SURVEY OF PERORAL ENDOSCOPY

FROM ITS ORIGIN TO THE PRESENT DAY.*

BY

IRWIN MOORE, M.B., C.M.EDIN.

THE first successful attempts to obtain direct vision of the oesophagus and bronchi were made by laryngologists, thus establishing their claim to include these regions in the domain of their specialty. Little of favour and encouragement was bestowed on early endoscopic attempts, hence progress was but slow, and the interest taken in it was only of an academic nature. The present proud position occupied by the method is largely due to such pioneers as Gustav Killian, who has been styled the "Father of Bronchoscopy," Chevalier Jackson, and others. It is no exaggeration to assert that there has been no greater development in the history of medicine and surgery than that of peroral bronchoscopy, for it has opened to view the whole length of the oesophagus, the cavity of the stomach, and the bronchial ramifications.

As recently as 1903 Jonathan Wright of New York spoke of the removal of foreign bodies from the bronchi as a species of legerdemain, when he learned of two cases at Freiburg in which foreign bodies in the bronchi had been successfully removed by the mouth. One of the patients was a child aged 6; the procedure was carried out under chloroform, and Wright says that it seemed to the inexperienced laryngologist little short of miraculous. A comparison of this with the present position of peroral endoscopy shows what enormous strides have been made.

The statistics of foreign bodies accidentally aspirated into the respiratory passages, and the consequent mortality at different periods, are very instructive. The mortality in the pre-laryngoscopic period was 52 per cent.; the laryngoscopic period reduced the mortality to 30 per cent. In the early days of bronchoscopy—1897 to 1908—the death rate was down to 13.1 per cent., while in the period 1909-10 this was further reduced to 9.5 per cent. By 1913 the death rate from this cause had fallen, according to Killian, to 8 to 9 per cent., while Chevalier Jackson gave, for various surgeons in the United States, a mortality of between 5.3 and 1.7 per cent., the latter figure having been achieved by himself in 182 consecutive cases of bronchoscopy for foreign bodies. In many cases recorded the foreign body has been either vomited or evacuated per rectum. In the large clinics, of 210 cases of foreign bodies in the oesophagus, 12 were evacuated, and all the remainder were removed by oesophagoscopy. Of 206 cases of oesophagoscopy for foreign bodies, in Jackson's hands, only 8 defied his efforts, and 4 of these died, one from advanced nephritis, while the oesophagus of the other three had been severely lacerated before he saw them.

The mortality in these cases in this country is considerably higher than the figures just given, since a number of cases are treated by such old methods as the bougie and probang before coming to the laryngologist. The profession has not yet fully appreciated the value of endoscopy in diagnosing diseased conditions of the gullet which have hitherto been unrecognized.

A large number of laryngologists have borne a share in bringing the method to its present efficiency, besides those outstanding men whose names are mentioned in this article.

It is nearly 120 years since Philip Bozzini of Frankfort designed an apparatus, the "light conductor," for looking into the dark cavities of the body. It was a convex vase-shaped stand, and its lamp-holder, of tin, was covered with leather, its upper third being uncovered brass. A candle inside one half of the lamp-holder gave the light, the other half having an opening in its posterior wall for the observer's eye. The candle light was reflected into the examining tube. At a later stage a concave mirror was fixed inside the lamp-holder. It was specially designed to view the urethra and rectum. The Medical Faculty of Vienna, asked by the Government to report on this, condemned it, stigmatizing it as a toy.

Eighteen years later John D. Fisher of Boston devised and used an endoscope consisting of lens and mirror, again illuminated by a candle. It had a concave mirror, three tubes, and two looking-glasses, and there was a mechanism for keeping the flame opposite the lens. Cylindrical tubes were united at right angles, forming an elbow-joint. A lens magnified the object to be viewed. The designer himself suggested that his instrument was "easily susceptible of improvement."

Ségalas (Paris, 1826) developed Bozzini's apparatus, constructing a urethro-cystic speculum for optical examination of the bladder and urethra. A polished cylindrical tube was open at its extremities for introduction into the urinary passages, and its length and size could be varied as required. Desormeaux, overlooking the work of Bozzini and Fisher, credited Ségalas with having originated the idea of an instrument for projecting light into deep cavities.

Bombolozini, an Italian, in 1827 devised a speculum for exploring the stomach, bladder, uterus, and rectum. Guillon spoke of this apparatus as a kind of camera obscura. There seems to be no record of any practical work having been done with this instrument.

John Avery, who was a surgeon at Charing Cross Hospital from 1843 to 1855, produced an apparatus with a frontal reflecting mirror to intensify the candle-light used, with a laryngeal mirror which was fixed to a speculum. He tried to view the vocal cords with it. At Avery's death the *Lancet* stated that he had been able by means of the apparatus to examine the ear, urethra, bladder, oesophagus, and larynx as probably no other surgeon had before him.

Desormeaux (Paris, 1853) produced an apparatus lighted by a gas-oxygen lamp, somewhat similar to Fisher's. In this the light was collected by a condenser, and fell upon

* Abstract of a paper communicated to the Section of Laryngology, Otology, and Rhinology of the Annual Meeting of the British Medical Association at Bath (July, 1925). The full text will be published, with illustrations, in the *Journal of Laryngology and Otology*.

a reflector which had an opening for the eye in the centre. Desormeaux was an indefatigable worker at endoscopy, and his work for thirteen years made it impossible for the profession to ignore what he did. He raised the use of the endoscope to a method; hence it is fair to regard him as the founder of endoscopy.

Horace Green (New York) in the following year proved the tolerance of the larynx to the passage of foreign bodies and instruments, and he passed a solution of silver nitrate through a gum-elastic catheter into tuberculous cavities via either bronchus. In his paper in 1860 on "The difficulty and advantage of catheterization of the air passages in diseases of the chest" he related 106 cases so treated, and he employed the method also in bronchitis and asthma. John Hughes Bennett (Edinburgh), in 1857, confirmed Green's work.

Sir Philip Crampton, a Dublin surgeon, who died in 1858, and was a great authority on lithotomy, also assisted in the development of endoscopy, but published no account of his work in this domain.

After Desormeaux's work little practical progress seems to have been made until Richard Cruise of Dublin, realizing in 1865 that the illumination in Desormeaux's apparatus was not adequate, designed a brighter light which enabled him to get a view of the uterus, and in the year following he published a paper entitled "The endoscope as an aid in the diagnosis and treatment of disease"; in this he showed that the utility of the instrument was not confined to the diagnosis and treatment of diseases of the urethra, but was valuable in any part of the body into which a straight tube could be introduced, such as the bladder, the uterus, and the rectum, as well as the auditory meatus, nasal fossae, pharynx, larynx, and, he hoped, also the oesophagus and stomach. This contribution of Cruise was the first definite mention in the literature of the possibility of endoscopic examination of the air and food passages; and it is of interest to note that the present-day endoscope, as represented by the models of Kirstein and Brünig, were identical in principle with the designs of these earlier pioneers.

John Brunton described, in 1865, "A new otoscope or aural endoscope," which he had designed four years earlier. It is extensively used even at the present day.

Stoerk and Semeleder of Vienna made, in 1866, the first attempt to examine the gullet by an instrument; this consisted of a pair of forceps having spoon-shaped blades, and a laryngeal mirror attached. After introduction of the instrument the laryngeal mirror was placed in the ordinary position. Only negative results, however, emanated from this experiment.

Julius Brück, a dental surgeon of Breslau, was the first to take advantage of the introduction of the galvanocautery in 1756 by Middlethorp as a source of light for examining cavities of the body such as the bladder and intestine.

John Aylwin Bevan published, in 1868, a description of various instruments which he had designed for examining the pharynx, larynx, and posterior nares, which instruments could be fitted to a lamp, and he also devised a tube for inspecting the gullet. Morell Mackenzie said that Bevan's work was obviously the result of work in the laboratory rather than in hospital wards, and that the instruments were of no practical value.

Kussmaul (Freiburg) in 1868 reported to the scientific faculty of his city the successful examinations he had made of the oesophagus, both normal and diseased, and to him has been attributed the first oesophagoscopy worthy of the name. He passed a straight rigid tube into the oesophagus with the aid of a Desormeaux urethroscope for providing the illumination. Kussmaul, by this means, is reported to have diagnosed a carcinoma of the thoracic oesophagus, and to have approached the cardia. His pupil, Müller, continued these experiments, and showed that a rigid tube 15 mm. in diameter could be safely introduced into the oesophagus of the normal adult. As Kussmaul did not publish his work, and had it not been for Killian, that work might have passed into oblivion.

Waldenburg (Berlin) designed an oesophagoscope in 1868 consisting of a gum-elastic tube 8 cm. long to which a laryngeal mirror was attached. He employed this

apparatus in a case of pharyngeal pouch, and was able to observe its walls and contents. Later he had an instrument constructed of metal instead of gum-elastic. There were two tubes arranged telescopically, each of them being 6 cm. in length, one playing on the other by means of a slot.

Trouve (Paris) attempted, in 1873, to improve the illumination by means of a "polyscope," a tube with a window fitted with an optical arrangement of prisms and lenses. Ledentu and Raynaud also used this instrument for oesophagoscopy, and with it they were able to diagnose a cicatricial stricture of the oesophagus near the cardia, while at about the same date Collin demonstrated endoscopically the function of a bull's stomach.

Edison of New Jersey, U.S.A., by inventing the incandescent lamp in 1878, advanced endoscopy still further, enabling Mikulicz, Kirstein, and others to improve the method of lighting at a later date and to introduce an examining tube.

O'Dwyer (New York) invented and perfected in 1880 intubation of the larynx, and later a large tube for facilitating the expulsion of foreign bodies from the lungs.

Morell Mackenzie designed, in 1880, a skeleton oesophageal tube, one which could be opened and closed. It consisted of handle, stem, and skeleton tube, the handle being connected with the stem by a movable knuckle joint. At the top of the skeleton tube was a slot into which was fitted a laryngeal mirror. The skeleton tube could be opened after it was inserted, the rings brought into the horizontal position, and the gullet expanded.

Stoerk, in 1881, renewed his oesophageal experiments, and described an instrument which was really an addition to that of Waldenburg. It was provided with a pilot or director consisting of a piece of elastic tubing, terminating in a small bag, which projected beyond the end of the oesophagoscope. When the bag had been inflated the instrument was passed into the gullet, when the air was allowed to escape and the pilot was withdrawn. But this and the Waldenburg instrument were designed for indirect examination, and so were failures.

Mikulicz of Vienna, in 1881, with the help of Leiter, designed an optical apparatus illuminated by an interior electric lamp of platinum wire, with a cooling arrangement, and to this were attached straight rigid tubes. By its aid Mikulicz was able to carry out important anatomical, physiological, and pathological investigations on the oesophagus, and these form the basis of our knowledge to-day. He also designed a gastroscope, attempting to examine with it the stomach of normal persons. But he was said never to have reached the cardia.

Stoerk, in 1887, made use of a long rigid tube, which he passed with the patient's neck in the extended position, thus doing direct oesophagoscopy. In the same year an improvement was made in the illuminating portion of the instrument by the Leiter-Nietz oesophagoscope. This had an internal lamp and a system of prisms.

Von Hacker (Vienna), in 1889, brought oesophagoscopy to such a pitch of perfection that it became of practical use, and his efforts deserve almost as much credit as did those of Mikulicz himself.

Gottstein of Breslau, in 1891, designed and used endoscopic tubes with an extra tube inserted in their walls, to produce suction. He also advanced oesophagoscopy under cocaine anaesthesia.

Von Hacker, in 1894, made inspections into the tracheo-bronchial region for diagnostic purposes.

Rosenheim (Berlin), in 1895, began to study the subject and used this instrument, and recorded having removed many foreign bodies from the oesophagus.

During the following years further improvements in the problem of illumination were introduced by Kirstein, Caspar, Leiter, Guisez, Brünig, Einhorn, Schreiber, Gluckmann, and Chevalier Jackson.

It now remained for Kirstein and Killian really to arouse the interest of laryngologists in peroral endoscopy, and from that time great strides were made on the subject.

Kirstein (Berlin), in 1895, saw the interior of the larynx without a mirror for the first time, using first a flat spatula and later a tubular one. With the flat spatula the necessary light was obtained from a forehead lamp attached

to a vulcanite head-band. The electric lamp was enclosed in a cylindrical box containing a plano-convex lens, through which the light was cast on to a mirror which was fixed at an angle of 45 degrees, with a central perforation for the observer's vision. Later, Kirstein used this lamp attached to his spatula, and it was known as "Kirstein's auto-scope"; with this it was possible to inspect the deep pharynx and larynx directly.

From 1896 onwards tracheoscopy and bronchoscopy can be said to have passed its introductory stage and to have become one of the accepted and established proceedings of surgical practice.

Killian of Freiburg, in 1896, began to devote himself closely to endoscopy, and soon adapted the oesophagoscope to the systematic examination and treatment of the trachea and bronchi. In 1897 he designed a tube spatula which made it easier to reach and inspect the interior of the larynx; also oesophagoscopic and bronchoscopic tubes of different calibres and lengths, and a short split laryngeal spatula to help the easier introduction of the tubes. He also contrived an extension of his bronchoscope for introduction while *in situ*, consisting of a section of tube of smaller calibre passed into the first tube. He showed that the air passages could be explored far beyond the bifurcation of the trachea, and that it was possible to straighten out the bronchi with rigid tubes. He also introduced the dorsal posture of the patient for endoscopic work, and he showed that the lower limit or orifice of the hypopharynx was represented by a definite sphincter at the lower level of the cricoid cartilage, and corresponding to the commencement of the oesophagus. Killian's demonstrations of bronchoscopy caused a profound impression, and was a stimulus to laryngologists in all parts of the world.

Mikulicz (Vienna) and Gottstein (Breslau), in 1896, reported successful cases of tracheoscopy; and Einhorn of New York, in 1897, issued the first publication in America on the subject of oesophagoscopy; while Georg Kelling of Dresden devised, in 1897, a segmented oesophagoscope which could be straightened when desired.

Coolidge of Boston, in 1899, removed a broken tracheal cannula from the right bronchus by lower bronchoscopy.

Gordon King of New Orleans, in 1899, described oesophagoscopy and its application to two cases, and an account of two foreign bodies impacted in the oesophagus.

Chiari (Vienna), in 1899, employed and demonstrated upper tracheo-bronchoscopy.

Schrötter (Vienna), in the same year, removed a lead seal from the second division of the right bronchus in a boy patient aged 12.

Killian, in 1900, cut in half, by means of a galvanocautery snare, a vulcanite dental plate without any metal part, which was impacted in the oesophagus near the cardia, at a distance of 35 cm. from the mouth, and it was removed by him in two portions.

Von Hacker recorded, in 1900, removing a number of foreign bodies from the gullet, and devised several instruments for oesophagoscopy; and von Mikulicz, a year later, published a similar record; while both Schrötter (Vienna) and Pieniazek (Cracow) reported work done on lower bronchoscopy. Einhorn of New York first designed the distal lighting principle, and a stylet or mandrin to assist the introduction of the tube.

Killian, in 1902, wrote a paper on "Direct endoscopy of the upper air passages and oesophagus," and read it at the Manchester meeting of the British Medical Association in that year, emphasizing the fact that now the oesophagus could be systematically searched from above downwards.

Glucksman (Berlin), in 1903, demonstrated an oesophagoscope which he had devised for distal lighting.

Fletcher Ingals (Chicago), in 1904, following the idea of Einhorn and Glucksman, employed a distal light on a separate carrier in a Killian tube.

Von Eichen, who was Killian's chief assistant, wrote, in 1904, his well known article on endoscopy. It covered all the work on the subject which had been done to date.

Brüning, who was also an assistant to Killian, was notable for the mechanical improvements he made in Killian's endoscopic methods, and for his pioneer work in the teaching of the specialty.

Coolidge, in 1906, published a paper on "Foreign bodies

in the trachea and bronchoscopy," reporting a collection of forty-nine foreign bodies which had been removed from the lungs, the mortality having been 8 per cent. Three of the four fatal cases in the list were in a serious condition at the time of the operation.

Chevalier Jackson, professor of bronchoscopy, etc., in Pennsylvania University, in 1904 combined the distal lighting principle and the stylet of Einhorn with the Killian tube, by means of an auxiliary tube in the wall of the main tube. At a later stage he dispensed with the stylet. In 1905 he designed a bronchoscope with two auxiliary tubes—one for the light carrier and the other for the suction tube—and in the following year a gastroscope; a year later still he published a book on *Tracheo-bronchoscopy, Oesophagoscopy, and Gastroscopy*, and subsequently included it in his later work, *Peroral Endoscopy and Laryngeal Surgery*. He is responsible for a prolific literature on these subjects.

Kahler (Vienna) removed, in 1902, a tooth-plate which was impacted in the oesophagus, and in 1904 he removed a piece of bone from the bronchus. In 1909 he designed, with Leiter, a panlectroscope, rendering easy the introduction of operating instruments.

Guisez (Paris), a name foremost in France in this work, reported in 1903 having removed a nail from a bronchus, and in 1905 he introduced a head-lamp consisting of three small bull's-eyes arranged in a circle. In 1908 he commenced to use radium for gullet cancer.

It was not long before British laryngologists began to adopt Killian's methods. Waggett, in 1903, was the first in this country to begin the study of endoscopy, and to employ Killian's tubes, with headlight; and the same year he diagnosed a malignant growth in the oesophagus. In 1924 he removed a tooth-plate, 1½ in. long and ¾ in. broad, from the right bronchus, by inferior bronchoscopy.

D. R. Paterson of Cardiff seriously took up endoscopic work in 1904, and in that year he removed a stay-eyeclet from the trachea of a child of 8 by Killian's tracheoscope, and later recorded other cases. In 1905 he designed and introduced his laryngeal forceps for the direct removal of laryngeal papillomata. In that year he removed a tooth-plate having four teeth and two hooks attached from a female aged 36, at the level of the suprasternal notch. In 1906 he contributed the first paper in this country on direct examination of the oesophagus and upper air passages. He also introduced a modification of Brüning's tubes to facilitate the easier passage of the tube through the larynx.

Mosher (Boston) began to use oesophageal tubes in 1904, and later designed a special oral oesophagoscope.

A. Coolidge, in 1904, published a paper on "The extraction of foreign bodies from the bronchi," and gave an account of the removals of foreign bodies he had carried out.

Exner of Düsseldorf was the first to employ, in 1904, the rays of radium salts and radium emanation for malignant disease of the gullet, and palliative results were claimed.

E. D. D. Davis first began, in 1905, to practise oesophagoscopy and bronchoscopy, with Waggett, employing Killian's tubes and Kirstein's headlight. In 1908 Davis recorded his first case of extraction, that of a farthing, from the oesophagus of a child aged 9 months. In 1914 he published a paper entitled "The importance of a very thorough examination in cases of foreign bodies alleged to have been swallowed or inhaled"; it was to show the dangers of delay in such cases.

Thomas Claytor (Washington) wrote a paper in 1906 on "Foreign bodies in the bronchi"; and Jefferson Faulder, in the same year, contributed one on "Bronchoscopy" and one on "Direct oesophagoscopy."

William Hill started this work in 1907, and in the following year removed his first foreign body. In 1909 he designed an improved direct-vision pharyngo-laryngoscope, with a lateral slot to facilitate operation. In the same year he started radium work for malignant disease of the gullet, and was the first in this country so to apply it. He has published a valuable series of contributions on the subject, and in 1912 he designed an improved radium apparatus for gullet cancer, having an adjustable collar to prevent displacement of the radium.

Herbert Tilley, in 1907, took up the methodical study of endoscopy, and the same year he removed a shawl-pin

2½ in. long from the left bronchus of a woman aged 23. He has also published a paper on direct bronchoscopy, one on direct examination of the larynx, and a report of numerous foreign bodies which he had extracted.

W. C. Howarth studied bronchoscopy and oesophagoscopy in 1907, and in 1912 he published the translation and amplification of Brüning's textbook, and in the year following he contributed a paper on "Some difficult foreign bodies in the air passages."

Irwin Moore commenced the practice of oesophagoscopy and bronchoscopy in 1908, and his work has been chiefly confined to the diagnosis and treatment of diseases of the gullet. In 1910 he designed a "universal" foreign body forceps, and cutting shears for dividing dental plates which had become impacted in the oesophagus. In 1916 he published a paper on the removal of foreign bodies from the oesophagus and bronchi, and described instruments which he had designed. He also published a plea for the abolition of the coin-catcher. In 1919 he published some statistics of end-results of pins accidentally inhaled into the lungs. In 1921 he designed tubes to allow proximal and distal lighting to be interchanged without disturbance of the tube *in situ*.

Thomas Halstead (Syracuse, N.Y.) published, in 1908, a paper on his personal experiences in the use of the bronchoscope, oesophagoscope, and gastroscope, with cases; Brown Kelly (Glasgow) and Ingersole (Cleveland) did likewise. While Gay French, in 1909, related the removal of foreign bodies from the oesophagus by Brüning's direct instrument.

Souttar and Theodore Thompson, in 1909, published a paper on "The gastroscope and its uses," describing a new form of apparatus they had designed.

Sir William Milligan, the pioneer of endoscopy in Manchester, started the work early in 1909, the year in which he first removed a foreign body from the oesophagus, and in 1920 he contributed a paper on "Some practical points in the removal of foreign bodies impacted in the food and air passages," exhibiting, when he read the paper, fifty foreign bodies which he had successfully removed.

Sir StClair Thomson (with whom Irwin Moore worked) successfully removed, in 1910, a tooth-plate which had become impacted in the oesophagus, and had remained at the bifurcation of the trachea two and a half years. In the same year Sir StClair removed a shawl-pin from the lungs after twenty-seven hours of impaction. In 1917 he removed a tooth from a secondary left bronchus, by means of tracheotomy and lower bronchoscopy, after he had made two attempts at removal by peroral bronchoscopy.

Killian, in 1911, published a history of bronchoscopy and oesophagoscopy: in that year also he brought in suspension laryngoscopy, and he described the process in London in 1913.

Claoué (Bordeaux), in 1912, following Killian's example, divided a vulcanite denture which had become impacted in the oesophagus 24 cm. from the aortic arch, by means of a galvano-cautery knife.

Glucksmann (Berlin) contributed a paper in 1912 on "The newer methods of extraction of foreign bodies from the air and food passages."

Thomas Guthrie, the pioneer of endoscopy in Liverpool, published, in the same year, a paper on twelve cases of removal of foreign bodies.

Logan Turner and J. S. Fraser (Edinburgh) published a paper, in 1913, on "The direct method of examination of the lungs, trachea, bronchi, and oesophagus, with illustrative cases." They also reported seven cases in which they removed papillomata from below the vocal cords by the direct method.

H. L. Lynah (New York) published, in 1915, two papers on these subjects, and in 1921 two further papers on the radiographical aspect of the question.

Somerville Hastings was the first to cut in half a vulcanite denture which had been impacted at the level of the aortic arch; it was so securely fixed that it could not be moved by forceps. He employed Irwin Moore's denture shears. In 1914 he successfully removed a half-sovereign from the right bronchus, and in 1918 he recorded having removed a piece of mutton bone through a tear or rent in the posterior wall of the oesophagus, which had been produced by a bougie that had been passed down the gullet

prior to the patient's admission to hospital. The patient recovered.

Gay French, in 1917, also divided and removed a denture in a similar way to Somerville Hastings, and complete recovery ensued.

Ellen J. Patterson (Pittsburgh) has made valuable additions to the literature of endoscopy.

In 1920 the oldest medical school in the United States, that of Pennsylvania, established the first chair and professorship for the teaching of bronchoscopy and oesophagoscopy, and Chevalier Jackson, in whose honour this was done, was made professor. Many veterinary schools have also taken up the teaching of endoscopy for application to animals. In the five years that the professorship has been in operation 400 students have taken the course.

Gabriel Tucker (Philadelphia), in 1923, was appointed associate professor on the subject at the Pennsylvania University, and in the following year he wrote a thesis on "Cicatrical stenosis of the oesophagus, with particular reference to treatment by continuous string retrograde bouginage with the author's bougie." In the same year he published an article on fifty cases of foreign bodies, and he has designed valuable bronchoscopic forceps.

Louis H. Clerf (Philadelphia) has also contributed articles on foreign bodies impacted in the food and air passages.

W. F. Manges (Philadelphia) published, in 1923, a paper on "The mechanism of physical signs, with special reference to foreign bodies in the bronchi," and in the following year one on "Atelectasis as a Röntgen sign of foreign body in the air passages." To him the profession is indebted for bringing to high perfection the x-ray diagnosis of non-opaque foreign bodies in the lungs.

Scott Ridout (Portsmouth) contributed a paper in 1923 on the subject and recorded five cases of removal of foreign bodies.

Crow (Brighton), in 1924, recorded his successful removal of part of a safety-pin by peroral bronchoscopy from a child.

Souttar, in 1924, published a paper on "A method of intubating the oesophagus for malignant strictures," in which he described a simple, close-spiral flexible wire intubation tube. The advantages were that food did not tend to cling to it, it did not cause ulceration, and it was retained without difficulty; sometimes it had been worn for a year. In 1925 he read a paper on "Cancer of the oesophagus."

T. McCrae (Philadelphia) delivered the Lumleian Lectures before the Royal College of Physicians, London, on "The clinical features of foreign bodies in the trachea and bronchi."

Harrison (Newcastle-on-Tyne), in 1925, removed a bead from the left superior lobe bronchus of a child aged 2½ years.

Frank Wilson (Newcastle-on-Tyne) devised, in the same year, an ingenious method of detecting non-opaque foreign bodies in the oesophagus by giving the patient small pledgets of cotton-wool soaked in barium or bismuth paste to swallow, followed by a radiogram, when the shadow is seen to be the shape of an inverted cone.

Endobronchial Therapy.

Endobronchial therapy was assured when, in 1907, Nowotony of Cracow discovered that adrenaline when applied bronchoscopically favourably influenced a case of bronchial asthma. He obtained a "lasting result" in seven out of eight cases so treated.

Ephraim (Breslau) confirmed Nowotony's observations, and worked at other endobronchial treatments in 1910. In this country Syme (Glasgow) has ably carried on Ephraim's work, and has been able to produce some striking results. The bronchoscopic method of applying medicaments will control haemorrhage from the trachea, also pain arising from growth there, and from wounds caused by foreign bodies.

W. F. Moore and R. M. Lukens (Jefferson College, Philadelphia) recorded, in conjunction with E. H. Funk, in 1923, their results from the use of autogenous vaccines prepared from secretions which were obtained bronchoscopically, along with the instillation of adrenaline, cocaine,

and normal saline into the bronchi. In the next year they also published an analysis of cases of pulmonary abscesses, including those which were complicated with bronchitis.

Ewart Martin (Edinburgh), in 1924, published his experiences of bronchoscopy in relation to lung diseases, and gave results of treatment, some cases having extended over one and a half years.

Howarth, in 1925, published, in association with Cassidy, a case of abscess of the lung and bronchiectasis treated by bronchoscopic aspiration and lavage.

Owing to successive researches and inventions, these methods have now become much simplified, and are part of the usual routine of the laryngologist. Success in this country has been largely associated with becoming accustomed to using the largest endoscopic tubes which can be safely employed in each case. Endobronchial therapy now offers a wide and expanding field for further research work.

THE ETIOLOGY OF DIVERTICULA OF THE INTESTINE.

BY

R. DAVIES-COLLEY, C.M.G., M.Ch., F.R.C.S.,
SURGEON, GUY'S HOSPITAL.

IN the interesting paper on intestinal diverticula, published in the *BRITISH MEDICAL JOURNAL* of January 23rd (p. 130), a prediverticular state of local inflammation of the colon is described which, it is suggested, is responsible for the formation of the diverticula.

The etiology of diverticula has for a long time been of special interest to me, and of the various theories put forward to account for them none have seemed very convincing. I have for some years believed and taught that inflammation is a probable factor in producing the condition, at any rate in some of the cases in which the colon is affected, and I therefore particularly welcome the paper as supplying confirmatory evidence. My reasons for believing diverticula of the colon to be due to an inflammatory cause were two in number:

1. The most common seat of diverticulosis is one at which evidence of chronic inflammation in the shape of peritoneal adhesions is very often found—that is, the lower end of the sigmoid flexure. Clinically also patients are frequently seen in whom the sigmoid is hard and tender, suggesting that a mild degree of inflammation is present. The obvious criticism will perhaps be made that if these signs of inflammation have anything to do with the liability of this part of the colon to form diverticula, diverticula should be still more common in the caecal appendix, where inflammation is far more frequent than anywhere else in the gut. The answer to this is that the appendix is prevented from being a common seat of diverticulosis by the greater relative thickness of its muscular covering, and also by the fact that its lumen is rarely distended sufficiently to stretch its walls, and therefore the final factor in the production of diverticula—internal pressure—is wanting.

2. The second reason was the outcome of an investigation which I made some years ago of a number of specimens of gut removed either by operation or after death from cases of diverticulitis, by which I hoped to be able to trace some definite causal relationship between the fat of the appendices epiploicae and the occurrence of diverticula. I discovered nothing that seemed to me at that time sufficiently convincing for publication, but my suspicions were aroused by the fact that in several of these specimens I found in the wall of the gut, extending for a distance of some inches from the inflamed diverticula, localized patches of inflammation, some of which were evidently of long standing, in the bases of attachment of the appendices epiploicae, whereas in places where the muscle fibres were in direct contact with the peritoneum and had no fatty covering there were no signs of inflammatory change.

It seemed to me probable that these inflammatory patches might be accounted for by a lack of free lymphatic drainage at the points where the intestinal muscle was coated with a thick layer of fat, and that there might thus be a twofold cause which determined the onset of diverticulosis—

first, an abnormally heavy deposit of fat in the appendices epiploicae; and secondly, an inflammatory process in the deepest portion of the fat, which in the course of time so weakened the muscle that it eventually gave way to the pressure exerted by the intestinal contents and allowed herniation of the mucous membrane to occur.

But whatever part inflammation may play in the production of the diverticula it must, I think, be assumed that the intestinal fat is in some way primarily responsible, for not only do the diverticula invariably occur at points where the intestinal wall is normally covered by fat and never where it is covered by peritoneum alone, but also an abnormal degree of adiposity is an accompaniment of diverticulosis to which nearly every writer on the subject has drawn attention, and in fact might almost be said to be a *sine qua non*. My experience has been limited to cases in which inflammation of the diverticula has occurred; of seventeen cases at Guy's Hospital of which I have notes, only two were in people not unusually stout, and both of these had passed through a period of obesity before the symptoms of diverticulitis manifested themselves. Therefore no theory of etiology can be held to be satisfactory which does not make the fat the starting-point in the process of which the herniation of the mucosa is the final outcome.

Three possible explanations occur to me, each of which I think is reasonable in that a parallel can be found for it in pathological processes occurring elsewhere in the body. They are as follows:

1. The subperitoneal fat weakens the intestinal wall by inducing a simple atrophy of the muscle from pressure.

2. The fat invades and separates the muscle fibres, and so produces weak spots. In this case the natural line of invasion would be along the vessels which penetrate the muscular coat, so that these would be the most likely points for herniae to occur.

3. The fat becomes infected, probably by the intestinal contents, and the muscle in contact with it is weakened by an inflammatory process.

In the light of the x-ray evidence now added to the reasons which I have given above there would seem to be good grounds for believing that this last alternative is the true explanation of most of the diverticula occurring in the colon, though some in the colon and perhaps most of those in the small intestine, where infection of the fat is less likely to happen, may be ascribed to one or other of the non-inflammatory causes I have suggested.

FISH AS THE SOURCE OF CERTAIN COCCIDIA RECENTLY DESCRIBED AS INTESTINAL PARASITES OF MAN.

BY

JOHN GORDON THOMSON, M.A., M.B., Ch.B.,
DIRECTOR, DEPARTMENT OF PROTOZOOLOGY,

AND

ANDREW ROBERTSON, M.B., Ch.B.,
ASSISTANT IN PROTOZOOLOGY,

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.

For some time the attention of the authors has been devoted to the study of protozoal parasites in the organs of fish, which, since they are a common item in the human dietary, were readily obtained from various retail fish shops in London. While the present communication is to be regarded as a preliminary note on this subject, there have been made already certain observations which appear to prove conclusively that three recently described coccidia, up till now presumed to be true intestinal parasites of man, are merely parasites of fish passed unaltered through the human alimentary tract.

Wenyon (1916) discovered a coccidian belonging to the genus *Eimeria* in human faeces, but, rightly doubting that it was not a true parasite of man, refrained from creating a new species until something more was known of its habitat and life-cycle. Dobell (1919), however, named it *Eimeria wenyoni*. It will be seen later that this organism is morphologically identical with *Eimeria clupearum* Thélohan, 1894.

In 1919 Dobell found and described another coccidian oöcyst in human faeces on which he bestowed the name *Eimeria oxyspora*. There is little doubt that this is really *Eimeria sardinae* Thélohan, 1890. In any event an oöcyst morphologically similar to *E. oxyspora* Dobell, 1919, is extremely common in the testes of herrings and of sprats.

Still more recently Snijders (1921) published an account of a coccidian oöcyst in human faeces, which Dobell (1921), having received a mounted specimen from Dr. Snijders, considered was different from *E. oxyspora*, and accordingly created a new species *E. snijdersi*. Regarding this latter species the authors (1922) have pointed out that it was probably not a true species, but was merely *E. oxyspora* distorted by the technique involved in its examination, which view is considerably strengthened by the present findings. In any case it cannot possibly be regarded now as a true parasite of man. Snijders presented two possibilities to explain the occurrence of this organism—namely, "contamination of the stool after its depository," or "the cysts might have been ingested with food or water and passed unaltered (or only slightly altered) through the alimentary canal," but nevertheless Dobell, in full knowledge of these remarks and on the evidence afforded by the re-examination of material on which various attempts at fixation and staining had been made, stated as follows: "It seems probable that the parasite is one which belongs to man himself. It is, however, somewhat remarkable that all species of *Eimeria* hitherto found in human stools are not only very rare, but apparently cause infections which are peculiarly transitory. Their cysts have suddenly appeared in the stools and then promptly vanished—never to return."

These three so-called human species—*E. wenyoni*, *E. oxyspora*, and *E. snijdersi*—have been accepted by medical men and have been incorporated in the medical textbooks on the authority of Dobell, who, unfortunately, had obviously overlooked the fact that over thirty years ago Thélohan (1890 and 1894) had described identical organisms in fish. It has been a gradually increasing custom among certain systematic zoologists to adopt towards medical men, who, after all, originally opened up the field for research in human protozoology, an attitude of superiority, and to deal with their work—work often carried out under most adverse conditions both as regards previous knowledge and difficulties of technique—in a manner decidedly caustic and unnecessarily crushing. Such destructive criticism is not encouraging for research, in which, in the nature of things, mistakes are bound to occur, as is well illustrated by the unfortunate errors in question.

Description of the Oöcysts in Fish obtained in the London Market.

Since there was a certain amount of evidence that the *Eimeria* found in man might possibly have been swallowed in the food, and since the article of diet most likely to contain these organisms was fish (vide Broughton-Alcock and Thomson (1919), who found *E. oxyspora* in the faeces of a patient whose diet, previous to the examination, was chiefly fish), a search was made of the organs of fish purchased at shops all over London. Eventually two species of coccidia were found in enormous numbers in the liver and testes of herrings (*Clupea harengus*) and in the liver of mackerel (*Scomber scomber*). Sprats (that is, young herrings) were also found to be heavily parasitized.

(a) *Eimeria sardinae* Thélohan, 1890.

In the testes of sprats, a dainty usually cooked and eaten entire, the oöcysts of *E. sardinae* were found in enormous numbers. They were also present in the "soft roes" of adult herrings, but were usually much scarcer. Their elastic oöcyst walls react easily to pressure, and thus their

apparent diameter is increased by the pressure of the coverslip. In specimens where the cysts were floating in a depth of fluid more or less uninfluenced by pressure the diameter was between 33μ and 40μ , but sizes varied for the above reasons up to 58μ . The sporocysts have the following dimensions— 25μ to 35μ long, by 7μ to 9μ broad (see Fig. 1). The oöcysts, sporocysts, and sporozoites are in every respect comparable to those of *E. oxyspora*.

FIG. 1.—Oöcysts of *Eimeria sardinae* from testes of herring and sprats. ($\times 900$ approx.)

The sporocysts were fusiform or whetstone-shaped. Further, the sporozoites have a spherical vesicular nucleus centrally placed, a clear vacuole-like area at one end (not the nucleus as indicated by Dobell) and crystalloid bodies.

This coccidian of fish is therefore identical with *E. oxyspora*, and with a little manipulation forms can be produced comparable to *E. snijdersi*. It is not a parasite of man, and can only be regarded as adventitiously passing through the human intestine. Feeding experiments are at present in progress. It is probably identical with *E. sardinae* Thélohan, 1890. This author did not figure the oöcysts, but he described them as spherical, with a diameter of 50μ , containing four fusiform sporocysts, which radiated from a granular mass of oöcystic residuum at one side of the cyst wall. He gave no measurements for the sporocysts nor the sporozoites, but his description is sufficiently clear to allow of its identification.

(b) *Eimeria clupearum* Thélohan, 1894.

This was encountered in about 100 per cent. of the livers of herrings, and was also present in the same organ of sprats and mackerel. The oöcysts are fully matured in the liver, in this respect being similar to *E. sardinae* in the testes, and varied in size between 18μ and 33μ . When suspended in fluid without pressure from the coverslip, they were mostly about 18μ to 20μ in diameter, but varied from 18μ to 33μ . They are spherical, and contain four oval sporocysts with blunt, rounded ends, measuring approximately 10μ by 7μ . In each sporocyst are two sporozoites. *E. clupearum* is identical with *Eimeria wenyoni* Dobell, 1919 (see Fig. 2).

SUMMARY AND CONCLUSIONS.

1. All the fish examined were from the London food supply.
2. Oöcysts of *Eimeria sardinae* Thélohan, 1890, are very common and often occur in enormous numbers in the testes of sprats and of adult herrings. Morphologically this is identical with *Eimeria oxyspora* Dobell, 1919.
3. Oöcysts of *Eimeria clupearum* Thélohan, 1894, occurred in the livers of herrings, sprats, and mackerel. These are identical with *Eimeria wenyoni* Dobell, 1919.
4. *Eimeria snijdersi* Dobell, 1921, is regarded as a degenerate or altered form of *Eimeria sardinae*.
5. *Eimeria oxyspora* Dobell, 1919, and *Eimeria snijdersi* Dobell, 1921, become synonyms of *Eimeria sardinae* Thélohan, 1890. *Eimeria wenyoni* Dobell, 1919, becomes a synonym of *Eimeria clupearum* Thélohan, 1894.
6. These coccidia are not true parasites of man, but are ingested in the food and pass unchanged through the intestine.

FIG. 2.—Oöcysts of *Eimeria clupearum* from liver of herring, sprats, and mackerel. ($\times 900$.)

Memoranda : MEDICAL, SURGICAL, OBSTETRICAL.

THE RELATION OF OBESITY TO DIABETES MELLITUS, AND SO-CALLED LIPOGENIC DIABETES.

A good deal has been written on the Continent in the past about "lipogenic diabetes"—that is to say, diabetes mellitus depending on or induced by obesity or a tendency to obesity. Everyone is, indeed, familiar with the common cases of mild diabetes in somewhat elderly fat individuals (especially Hebrews) in which the prognosis is usually good and in which the urine often becomes free from sugar under simple dietetic treatment. Such cases seem to favour the view that diabetes mellitus may sometimes be of lipogenic origin. The true explanation, of course, may be merely that two metabolic disorders, obesity and diabetes mellitus, often tend to occur in the same individuals and to run in the same families. In some cases the diabetes mellitus is apparently grave enough to prevent the occurrence of obesity, which would otherwise be present—that is to say, it prevents a constitutional (possibly familial) tendency to obesity from manifesting itself. The tendency to obesity in such cases remains latent because grave diabetes is present. It is in this way that one can explain the occasional occurrence of obesity in grave cases of diabetes mellitus when the latter is successfully kept under by insulin treatment. The insulin prevents the waste due to the chief metabolic defect, and enables the patient to become abnormally fat on a diet of relatively low calorie value. Such cases are, I think, examples of a latent constitutional tendency to obesity kept in check by grave diabetes mellitus, but becoming manifest when the diabetes mellitus is, so to speak, suppressed by insulin therapy, which may be, indeed, of use in the treatment of non-diabetic emaciated patients of certain kinds; in the diabetic class to which I refer, however, the insulin actually, by its successful employment, produces obesity (which is hardly desired), though a diet of relatively low calorie value is maintained.

HYPERGLYCAEMIA AS A CAUSE OF PRURITUS. VULVAE.

IN view of the section on skin complications in Professor Nixon's illuminating lecture on insulin treatment of diabetes, reported in the *BRITISH MEDICAL JOURNAL* of January 16th, the following case may be of interest.

An unmarried woman, aged 56, was admitted complaining of irritation and stinging pains about the vulva, so severe as frequently to prevent sleep. The condition had been present for four years, and she had been subjected to the usual forms of treatment, including high frequency. Locally there was slight thickening and darkening of the integuments, probably due to prolonged irritation and to the application of various remedies. Glycosuria had never been observed in the patient or her relatives, but she stated that she was still living on a diet prescribed for rheumatism three years before admission. This contained very little meat and no sugar, and was not such as to tend to cause hyperglycaemia.

On admission the urine was sugar-free, but the blood sugar was 0.18 per cent. The patient was given ordinary full diet for two days, when the blood sugar rose to 0.19 per cent., the urine remaining clear. The diet was now reduced to one containing 18 grams of carbohydrate and yielding 400 calories a day. When the blood sugar had dropped to 0.08 per cent. the diet was gradually increased till the patient was receiving 12.5 calories per lb. of body weight. The blood sugar was now 0.115 per cent., and the pruritus had entirely disappeared. When the diet, and consequently the blood sugar, were increased beyond these limits there was a return of the symptoms, and as the patient found the mixed diet giving 12.5 calories per lb. weight sufficient for her needs, and more generous than that on which she had been subsisting previous to admission, she was dismissed after sixteen days, free from symptoms. When last heard from she was keeping to the prescribed diet and had remained free from irritation and also from rheumatism.

There can be little doubt that in this case the slight hyperglycaemia, though not manifest as glycosuria, was the cause of the pruritus.

My thanks are due to Dr. Alice J. McLaren, gynaecological surgeon, for permission to publish this note.

EVELYN MCPHERSON, M.B., Ch.B., D.P.H.,
House Surgeon, Redlands Hospital for Women, Glasgow.

VAGINAL CALCULUS.

I SHOULD like to record another case of vaginal calculus. I removed a calculus from the vagina of a child aged 10, a paraplegic, and an inmate of Yaffon Hall Institution for Mental Deficients, in January, 1918. It was the size of a large walnut, and was removed without difficulty. There was no vesico-vaginal fistula, and the suggestion made by the late Professor Shattock, to whom I sent the specimen, was that it was caused by the constant trickle of urine into the vagina, owing to incontinence and the patient lying in the dorsal position.

The specimen, I believe, is now in St. Thomas's Hospital museum.

CONGENITAL HYDRONEPHROSIS IN A NEWLY BORN INFANT.

NUMEROUS cases of congenital hydronephrosis have been described, but most of them were in advanced stages of dilatation and the primary etiological factors could not be easily deduced. A short account is given here of congenital hydronephrosis in a stillborn infant in which the dilatation is not very great and the causative factor can be demonstrated; it has, therefore, been thought to be of sufficient interest to warrant its publication.

The large intestine, in this child, passed from the right iliac fossa upwards, backwards, and to the left to the splenic flexure. The part representing the ascending colon was, as is usual, very short, and there was a typical infantile caecum and a long appendix; it was, however, situated much lower than usual and lay in the iliac fossa. The first part of the oblique portion of the gut had not acquired its usual relation to the duodenum, but crossed the lower pole of the kidney, to which it was firmly bound by strong fibrous tissue. This part of the gut was a narrow cord-like tube with an extremely narrow lumen; it was, further, bent upon itself almost at right angles. The remainder of the colon, beyond this constriction, was greatly dilated and filled with meconium. On dissection, the ureter was found to pass downwards over the anterior surface of the lower pole of the kidney and to be compressed between it and the cord-like portion of the gut. Above this point, the pelvo-ureteric junction, the ureteral pelvis was greatly dilated, forming a hydronephrosis of the pelvic type, and there can be little doubt that this condition was due to the compression of the ureter by the gut.

RICHARD H. HUNTER, M.D., M.Ch.,
Lecturer in Anatomy, Queen's University, Belfast.

PULMONARY EMBOLISM FOLLOWING OPERATION FOR CATARACT.

I HAVE just reread Dr. Wynne Parry's interesting account (*BRITISH MEDICAL JOURNAL*, October 10th, 1925, p. 649) dealing with the above condition. What would appear to be an almost identical case occurred a few days ago at the County Hospital, Lincoln.

A married woman, aged 75, was admitted for cataract extraction on January 8th, 1926. She had had a preliminary iridectomy some months ago. The left lens was extracted bloodlessly and without difficulty on January 11th. The anaesthesia was produced by cocaine and adrenaline. A very small conjunctival flap was made. The operation was followed by practically no reaction in the eye, and the wound healed perfectly. A certain amount of debris was left in the anterior chamber.

Owing to there being a heavy rush of emergency work in the ward (a general one) the patient remained in bed for five days instead of the usual three. On the sixth day after operation, while completing her dressing, and while sitting at the edge of the bed, she suddenly became very pale, and complained of pain in the chest and difficulty in breathing. She collapsed on to the bed, with respirations becoming slow, irregular, and laboured. Respirations ceased in two minutes, the patient dying in extreme cyanosis.

I think this case also lends further support to Mr. Lockhart-Mummery's recent statement that the fatal clot forms, not at the site of the operation, but in all probability in the great veins of the lower abdomen, and that this condition is brought about by stagnation. *Post-mortem* examination was refused.

CLINICAL AND SCIENTIFIC PROCEEDINGS.

SOUTH WALES AND MONMOUTHSHIRE BRANCH.

The Subcutaneous Tuberculin Test.

A CLINICAL meeting of the South Wales and Monmouthshire Branch was held at the Swansea General Hospital on January 27th, Dr. R. J. COULTER being in the chair.

Dr. A. CLARKE BEGG read a paper on the value of the subcutaneous tuberculin test in the early diagnosis of pulmonary tuberculosis, and said this was particularly helpful in cases when no definite physical signs were present. The test should not be employed if the patient's temperature was above 99° F., if haemoptysis had occurred recently, nor in the presence of serious renal or cardiac disease. The danger of causing extension of the disease if used with these precautions was practically non-existent. Positive results had, however, been obtained in syphilis, leprosy, actinomycosis, and possibly in hydatid cyst. The technique was as follows: rest in bed was enforced for forty-eight hours, with four-hourly temperature readings, and an injection was then given of 0.001 c.cm. of old tuberculin. If the temperature rose within twenty-four to thirty-six hours to over 100° F. the reaction was positive. If this did not occur an injection of 0.002 c.cm. was given forty-eight hours after the first, and in the absence of a reaction a dose of 0.005 c.cm. was given after the lapse of another forty-eight hours. If reaction did not occur the result was taken as negative. If at any stage the reaction was uncertain the previous test was repeated. Reaction should be judged, not only by a rise of temperature, but by the occurrence of general malaise, local inflammation, and the presence of focal signs of the disease.

The Venous Pulse.

Dr. G. ARBOUR STEPHENS, in a paper on the pulse, with special reference to the production of the venous pulse, said that it was with great difficulty that the majority of medical practitioners gave up the idea that the arteries distended when the pulse wave was at its height. Most of them had the impression that a pulse wave was analogous to the passage of a rabbit along the inside of a cobra. What really happened was that the arteries filled with blood constituted "cords" ready to transmit impulses conveyed to them by the jerk of the heart's beat, as occurred when piano strings were struck by the hammers. Because the piano strings were taut the vibrations were rapid and the waves of simple construction, but when jerks were conveyed to a cord held loosely the waves travelled more slowly and were more complicated. When the end of a long cord, like that used for marking a tennis court, was fixed to the ground by a peg, pulled, and let go suddenly, waves were formed and transmitted along the whole length of the cord while it was falling to the ground. When fallen, the cord retained the shape of the waves, which in form were those considered typical of a sphygmographic tracing. If instead of the marking cord a rubber tube was filled with sand, and allowed to fall after being pulled, the waves were very much simpler in shape. It was important to note that the "sphygmographic" waves obtained on the cord depended for their shape on the vigour of the pull and the suddenness of the "let go," while one observed that the form of the waves changed from the free end to the fixed. The thickness of the cord represented the pressure in an artery, and the jerk and "let go" of the cord comprised the conveyance of amplitude and velocity to the pulse wave. In the rubber tube filled with sand the "pressure" was high and the waves were simple, while in the different sized cords varying in consistency (or "pressure") the curves became more and more complex. By the above method one obtained the waves retained *in situ*, whereas in the case of those taken by a sphygmograph the picture was merely an indirect one, though on comparison there was a close resemblance. After Dr. Stephens had made his cord experiments he saw a reference to work by Dr. Crighton Bramwell, wherein he described tracings obtained in tubes

which had been waved by a mechanically driven projector. Dr. Stephens thought that his own results were complementary to those obtained by Dr. Bramwell, whose excellent summary was applicable to the speaker's results. This method of propagation of waves along arteries or "cords" had an important bearing on the venous pulse. No pulse was due to the distension of blood vessels by the impelled blood, and consequently there was no distension of the jugular vein; what happened when there was a venous pulse was that waves were transmitted along the jugular. The question was how those waves were propagated. Even if the auricle, when contracting, drove the venous blood backwards, it was now known that there was no intermittent distension of the vessel even if the tricuspid valve leaked entirely: what propagated the wave, or, in other words, what gave the jerk which caused a wave to travel along the jugular vein? When considering the beat of the heart one had to view the cardiac apparatus as a whole and remember that the pericardium and its contents must be considered. In 1915 Dr. Stephens had discovered that there was a negative pressure in the pericardial cavity, whereby a suction action held the fluid under control during health. In heart disease this negative pressure and suction action got less and less, with the result that the fluid was less under control, and during each beat of the heart moved freely, the free movement conveying a jerk which started a wave or venous pulse. The venous pulse, however, was not always present in those cases where it was expected, and the explanation for this was of an anatomical nature. As was known, the pericardium at its reflection surrounded the aorta and pulmonary vein, but only partly embraced the vena cava; this partial embrace, however, varied, and when there was a full embrace the pericardial fluid, under diminished suction action, swung up to the vena cava and communicated the jerk necessary to produce the so-called "venous pulse."

Mr. C. L. ISAAC showed a case and gave notes of six consecutive cases without mortality of Dobson's operation in tuberculosis of the abdominal glands.

Several other interesting clinical cases were exhibited by the staff of the hospital.

ULSTER BRANCH.

The winter meeting of the Ulster Branch of the British Medical Association was held in the Medical Institute, Belfast, on January 21st; the President, Dr. D. P. GAUSSEN (Dunmurry), occupied the chair.

Dr. FOSTER COATES showed a patient with acromegaly. He pointed out that the patient was very anaemic, which was secondary. The x-ray examination showed some thickening about the sella turcica, and the optic discs were normal; there was a diminution of sugar tolerance but no glycosuria. He gave a full description of the anatomical and physiological peculiarities of the pituitary body with its divisions and the difficulty of differentiating its function.

Dr. W. CALWELL asked if any investigations had been made by lumbar puncture in these cases, as the pituitary fluid normally flowed into the meningeal cavity. Dr. BOYD CAMPBELL suggested that the pituitary affection was tuberculous, as the patient had scars in his neck due to removal of glands. Dr. J. S. DARLING also spoke.

Professor ANDREW FULLERTON read a short paper on operative treatment of hernia in infants and young children, based on his results in the out-patient department of Queen Street Hospital for Sick Children, with a comparison with operations in the wards and in private practice. The paper is printed in full this week at page 274.

Dr. E. C. THOMPSON (Omagh) congratulated Professor Fullerton and remarked on the great advance in this operation. Dr. J. S. DARLING (Lurgan) said that he now constantly operated on these cases: he used friar's balsam instead of collodion and found it equally good. The CHAIRMAN said that a large number of these infantile cases of hernia disappeared spontaneously or with the help of some old-fashioned aids. Professor Fullerton, in reply, said that many patients in whom the hernia had disappeared showed a hernia on effort in later life.

Mr. P. T. CANNIBIE and Dr. J. SLYTH read a paper on the surgical treatment of exophthalmic goitre. Mr.

Crymble gave a description of the anatomy of the thyroid gland: the superior thyroid artery supplied the supporting structure, the inferior artery the secreting tissue. A mid-thyroid vein was apt to be torn in dislocating the gland, and so was of importance. Great difficulty was experienced in avoiding injury to the recurrent laryngeal nerve, and so a pad of gland was left on either side of the trachea which protected the nerve, and at the same time the parathyroid glands. The legitimacy of the operation was based on the claim of the surgeons that they obtained better results. X-ray treatment had been advised between the operation of removal of the gland and tying the arteries, but if it failed adhesions were left which increased the difficulty of subsequent removal. It was difficult also to fix the exact dose: excess might cause burns and myxoedema. There was a difference of opinion as to whether the pathological condition was an excessive secretion, a "hyperthyroidism," or an excessive demand, resulting in a "dysthyroidism." The three types were: (1) Graves's disease with a uniform enlargement, (2) a toxic adenoma with little exophthalmos and nodules in the gland, and (3) a secondary affection, starting with an ordinary goitre, and later showing symptoms of intoxication. The safety of the operation was steadily improving: Crile had reduced his mortality to 1 per cent., Mr. Crymble had had fifteen cases with no deaths. The operation itself varied with the operator: some left the back layer over the nerve, some the apex, and some tied the vessels beforehand.

Dr. SMYTH said that the mortality depended much on the previous care and examination of the patient; if the basal metabolic rate was going up there was danger, but if it had been brought down by iodine and rest the risk was much less; this might take a couple of weeks to four months. The methods adopted were general hygienic quiet, no worry or excitement, and the exhibition of iodine, 15 minims of Lugol's solution thrice daily. If there was auricular fibrillation digitalis was given, and if a sedative was needed morphine might be used. Many cases required that the operation should be done in two stages: in the first the arteries were tied. After the operation there was always some hyperthyroidism, and iodine should be successful in combating it. If the iodine was vomited Dr. Smyth used colloidal iodine intravenously, and gr. 1/240 of Nativelle's digitalin subcutaneously. The chief danger was in the first twelve hours.

Professor FULLERTON described a case of cure after removal of septic tonsils. Professor LINDSAY asked for directions when to operate, what was the later history after operation, and the natural history of untouched cases. Dr. McKISACK said that his experience did not warrant universal operation. Mr. CRYMBLE, in reply, said that even ligaturing might give rise to a reaction, that there was a danger in postponing, and that three-fourths of cases always showed some stigmata although cured.

Reports of Societies.

PAIN IN THE RIGHT ILIAC FOSSA.

At a meeting of the Medical Society of London on February 8th a discussion was held on pain in the right iliac fossa; Sir HOLBURN WARING, president of the society, was in the chair.

Mr. H. W. CARSON, opening the discussion, said that there were many conditions besides chronic appendicitis which might cause right iliac fossa pain. One of the common causes of such pain in which a wrongful diagnosis of appendicitis might be given was muscular strain, particularly in young girls keen on games, such as netball and lacrosse, and in middle-aged men who were beginning to put on weight and in whom the pain was due to a commencing inguinal hernia. A frequent cause of right iliac fossa pain was trouble in the urinary tract; a stone in the ureter was perhaps the most likely to be overlooked. Another cause was tuberculous glands in the mesentery, and yet another, tumours of the colon. Stricture in the

left colon, as a result of back pressure, might produce right iliac pain, and this should always be borne in mind in a case of such pain with distended caecum in a constipated patient over 50. Women of spare build and with the characteristic carriage due to skeletal defects often complained of constant dragging pain in the right iliac fossa, which was relieved by recumbency. These patients had constipation, poor appetite, loss of energy, and sometimes nervous irritability, the abdominal wall was poor, and the kidneys prolapsed. He suggested that the pain in some of these postural cases might be due to the dragging effect exercised by a mobile colon upon a highly vascularized membrane in its vicinity, or that another thicker membrane obstructed the lumen of the ascending colon when the patient was erect. The operation of releasing these bands and fixing the ascending colon had not met with the success it should have done if this had been the cause of the trouble, but the removal of the appendix had been attended with even less success. With regard to chronic appendicitis, the idea must be dismissed from the mind that this could be diagnosed from right iliac fossa pain alone; the true symptom was appendicitis dyspepsia. Radiologists were not quite agreed as to the x-ray indications of chronic appendicitis. If the appendix was not visible after the barium meal the question arose whether the lumen was so obstructed that the barium could not enter; if it was seen, the question was whether the peristaltic action was abolished. Tenderness over a visible appendix was of no definite import whatever, because between the appendix and the leaded glove was the eleventh nerve entering the sheath of the rectus. In Mr. Carson's opinion, pain confined to the right iliac fossa should not be considered as due to appendicitis, especially in the absence of previous severe attacks, until the most painstaking investigation had disproved other possibilities.

Dr. A. F. HUNST thought that the explanation of numerous mistakes in diagnosis was want of care; a thorough investigation of the whole alimentary canal ought to prevent the vast majority. Quite apart from the mistake of removing an appendix not diseased, it was not at all uncommon for chronic appendicitis to be associated with disease in some other part of the abdomen. In 40 per cent. of cases of chronic appendicitis confirmed by operation achlorhydria was present, which meant that gastric digestion did not occur, so that there was a pre-disposition to intestinal infection and a variety of complications. Appendicitis was very frequently associated with chronic cholecystitis, and with gastric and duodenal ulcer. A not uncommon condition, found in many who had been to the East, and in some who had not been abroad at all, was amoebic infection of the caecum, associated with pain on the right side owing to chronic hepatitis. The greatest help to the diagnostician was afforded by x rays, with which it was possible to see the appendix in 100 per cent. of normal people and in 80 per cent. of people with chronic appendicitis, but a proper technique must be used. The radiograph by itself was of no use, there must be screen examination. He demonstrated how by careful palpation under the screen appendicular tenderness could be localized. In many cases in which, after removal of the appendix, right iliac fossa pain persisted the trouble was said to be due to adhesions, but he was doubtful whether adhesions in this part ever gave rise to symptoms, and still more doubtful whether ileal kinks and stasis had any importance. A pelvic caecum, again, was not a pathological condition; it was often seen in normal individuals. In all suspected cases inflation of the colon should be performed, combined with x-ray examination, and unless one or both of these were definitely positive a diagnosis of appendicitis should not be made. Cases of tuberculous infiltration limited to the end of the ileum often simulated appendicitis, but on examination with x rays the ileum would be found to be the tender point, with sometimes part of the caecum, and the appendix free from tenderness.

Dr. T. WATTS EDEN said that the conditions in which the gynaecologist was interested and which caused pain in the iliac fossa might, of course, produce such pain on either side, not necessarily the right side. But in chronic

salpingitis the appendix was involved in at least 50 per cent. of the cases, and was removed by the gynaecologist in quite half the cases in which he had to operate. The involvement of the appendix appeared to be secondary, and might be slight, taking the form of thin bands of adhesion between the inflamed tube and the appendix. The conditions under which one met with acute salpingitis were two: septic infection following childbirth or abortion, and gonorrhoea. In the first case the circumstances in which the acute abdominal symptoms occurred drew attention to the possibility of the Fallopian tube being infected, and there was little risk of the diagnosis going wrong, but this was not so with gonorrhoea. It might be said that it did not matter, because there must be an operation in both conditions. But the fact was that these acute gonorrhoeal tubes showed a very great capacity for recovery; his practice was not to attack an acutely infected tube at once, but to give it a chance to settle down. Hence diagnosis was important. It happened occasionally that a tube became acutely infected from an acute appendicitis. The classical instance of this was recorded by Sir (then Mr.) John Bland-Sutton twenty years ago, when, in a case in which he had removed both tube and appendix, he demonstrated a fistulous connexion between the two. There were other conditions of the tube which might lead to somewhat similar symptoms; one of these was torsion of the pedicle of the tube; a tube which was dilated and not adherent was capable of twisting just like an ovarian cyst. With regard to the ovary as a cause of pain, he had kept this until last because he thought it least important. There was a good deal of loose talk about ovarian pain, and the pain was sometimes attributed to ovarian neuralgia or congestion. Apart from the fact that the ovaries were generally more or less involved when the tubes were infected and inflamed, the conditions which caused pain in the right ovary were practically limited to two different kinds of haemorrhages—one from the ovary in ovarian pregnancy, and the other into the corpus luteum, generally associated with a diseased or cystic condition of that body. In conclusion he described a case of a woman, aged 24, who suffered from severe pain in the right side which she attributed to a fall six months previously. No cause could be found, but, the pain persisting, an operation was done, and a sewing needle was discovered transixed in the right ovary. It appeared that at the age of 14 she had swallowed a needle, which no doubt had lodged in the pelvic cavity, and as a result of the fall had been jerked into the ovary. If there was nothing new under the sun, there was always room for some novelty in the sheltered recesses of the abdomen.

The PRESIDENT agreed with Dr. Hurst as to the unsatisfactory character of the results of operation for bringing up the caecum from the pelvic cavity and fixing it at a higher level. His experience of these operations was that the great majority of patients were not appreciably benefited. With regard to tuberculous disease of the lower part of the ileum, on more than one occasion when appendicitis had been diagnosed he had found that the appendix was to no material extent diseased, but there was a tuberculous condition of the adjacent portion of the bowel. Mr. J. E. H. ROBERTS agreed with what had been said as to the uselessness of fixation operations of mobile organs. He also recalled that shortly after Sir John Bland-Sutton's discovery he himself had come upon an acute inflamed appendix adherent to the right Fallopian tube, which was also inflamed. Dr. GORDON GOODHART thought that persistent pain after the removal of the appendix, or indeed after any chronic abdominal trouble, might be due to spasm of the colon. Mr. T. H. OPENSHAW considered that adhesions of the omentum to the scar, or to a commencing hernia, were the most frequent cause of pain after operations on the appendix.

Mr. CARSON, in reply, said that adhesions of the omentum to the scar were often found when the abdomen was opened again, but whether these gave rise to pain he was not sure. On the general question of fixation operations, he declared that it was very much better to free organs which were abnormally fixed than to fix organs which were abnormally free.

DIPHTHERIA AND SCARLET FEVER.

At a meeting of the Medical Officers of Schools Association on February 5th Dr. R. A. O'BRIEN gave an address on diphtheria and scarlet fever.

Dr. O'Brien drew attention to the rarity of these two diseases in preparatory and public schools. The percentage of boys at various schools who had before the end of their school career suffered from diphtheria varied from 4 to 9; for scarlet fever the figures were 1 to 3. Most of these attacks had occurred before entry at preparatory schools. The possibility of these two diseases, however, was constantly present in the mind of the school medical officer; and it was chiefly in connexion with diagnosis that modern methods could help most. (The Schick test was described, and a number of medical student volunteers showed various Schick and Dick reactions to the meeting.) The Schick test result in the great majority of ordinary schoolboys could be read with ease twenty-four hours after the test. If there was any doubt, a daily record of size and colour for several days enabled a decision to be made. The perplexing pseudo-and-positive reactions were rare, and could generally be read with certainty at ten to fourteen days after the test. In rare cases the speaker had had to take blood and titrate it for antitoxin. When a suspicious sore throat was seen the Schick test, if negative, indicated clearly in the ordinary case that the disease was not diphtheria, for all patients with typical attacks of diphtheria gave positive reactions. Swabbing and overnight culture diagnosis might lead to error. Even if the bacilli from a "slightly suspicious" throat were virulent, one could not be certain, unless the Schick reaction were positive, that the patient was suffering from diphtheria. In doubtful cases it was possible to compromise by performing the Schick test and swabbing, and, if desired, giving antitoxin five to six hours later, when it would not interfere with the development of the Schick reaction.

In the control of school epidemics the first reliance should be placed on the Schick test. The ordinary procedure was to swab all contacts and segregate the positive reactors. The speaker had seen a Schick-negative carrier with very large numbers of virulent bacilli in his throat isolated in a small room with Schick-positive, and therefore susceptible, children—a highly dangerous position. If antitoxin was given to all contacts the epidemic was stayed, but cases might again occur in three weeks when the passive immunity had faded. The application of the Schick test enabled one to gain a confident control of the situation in twenty-four to forty-eight hours. The susceptible positive reactors were watched carefully for any slight symptoms, while among the negative Schick reactors was sought the carrier responsible for the outbreak. Diphtheria had been practically abolished from among the staffs of several large infectious hospitals, such as those under Dr. Harries at Birmingham, Dr. Kinloch at Aberdeen, and Dr. Benson of Edinburgh. It appeared that in the staffs of the London fever hospitals there had occurred from 100 to 200 cases of diphtheria each year until Schick testing and active immunization had begun to be applied a few years ago. Within the next year or two the disease would probably have been abolished from the Metropolitan Asylums Board's ward staffs. It was hoped that the "diphtheria prophylactic and indicating mixture" prepared recently by Glenny in guinea-pigs would enable one to control satisfactorily the testing and immunizing of human beings. Dr. E. R. Harries had made a number of observations which showed that the mixtures already prepared indicated approximately the same level of immunity as the Schick test, and at the same time, when given intradermally in a dose of 0.2 c.cm., acted as immunizing agents. It was likely that in the near future the process of immunization would consist in a periodical repeated intradermal injection until the Schick reaction produced by it was negative; this would shorten and simplify the procedure considerably.

Scarlet Fever.

At present "swab diagnosis" did not help, for it was not possible to identify with certainty the scarlet fever streptococcus, short of producing skin lesions with its toxin neutralizable by specific antitoxin; this was a troublesome

procedure. The Dick test generally resembled the Schick test, but conclusions must be drawn with great caution, for though the great majority of early cases of scarlet fever gave positive reactions, all did not do so. Nearly all gave a positive Schultz-Charlton test, showing local blanching when 0.2 c.cm. of diluted scarlet fever antitoxin was injected intradermally into an early scarlet fever rash. If an early "doubtful scarlet fever patient" gave a negative Dick reaction and a negative Schultz-Charlton reaction, the disease was almost certainly not scarlet fever. Convalescent scarlet fever patients developed antitoxin in their blood during convalescence; if, therefore, the blood of the suspected patient ten days after defervescence showed no blanching when injected into other scarlet fever patients, the diagnosis of "not scarlet fever" was justified. If desired, passive immunity could be produced by giving 10 c.cm. or less of a reasonably good scarlet fever antitoxin; thus, if desired, all contacts could be protected. Treatment with scarlet fever antitoxin was apparently successful. If given early in adequate dosage to patients with "hypertoxic" scarlet fever, the antitoxin cut short the disease. Concentrated serum promised to have the same effect in smaller doses. It was apparently possible to immunize positive Dick reactors and make them negative within a few weeks. How high and how lasting the immunity it was not yet possible to state, for the work in England was yet too new, but it was fairly clear that active immunization was practicable.

ARTIFICIAL PNEUMOTHORAX IN PHTHISIS.

At a meeting of the Brighton and Sussex Medico-Chirurgical Society on February 4th, with Mr. H. J. WALKER, the President, in the chair, Dr. DONALD HALL read a paper on the treatment of pulmonary tuberculosis by artificial pneumothorax.

Dr. Hall said that during the past six years he had established an efficient collapse in fifteen patients. Difficulty was found in obtaining material, for in hospital practice patients were now under the care of tuberculosis officers and came rarely to the out-patient department, while in private practice most cases were in sanatoriums or under the care of specialists. In this country artificial pneumothorax had not yet received the recognition which it deserved, for while applicable only to some 5 per cent. of patients it offered to them hope denied by any other methods. The apparatus he used was Vere Pearson and Lillingston's, which, although rather cumbersome in size, was simple and easy to use and easy to keep clean. For the initial puncture he preferred Riviere's trocar and cannula. In the selection of cases not only the extent but also the activity of the disease in the "healthy" lung must be considered. In acute cases especially care must be taken not to produce too high pressures, which would embarrass the sound lung; the optimum pressure was the minimum which kept up collapse. There had been a tendency of late to suggest that partial collapse might be preferable to complete. Of this he had had no personal experience; in his three cases in which collapse was incomplete but yet therapeutically adequate it had been impossible to obtain complete collapse of the lung owing to pleural adhesions, and up to the present he had always aimed at bringing about complete collapse. The decisive test of this was the absence of respiratory movement on the fluorescent screen. In four patients, otherwise suitable, pleural adhesions had balked him completely. He had met with one instance of pulmonary embolism in a patient who was having her last refill prior to leaving hospital for her home in the country. About a minute after withdrawing the needle conjugate deviation of the head and eyes occurred, and the patient had an epileptiform fit. She recovered, but with permanent hemiplegia, and the treatment was discontinued. Presumably the needle had perforated an adhesion containing pulmonary tissue, for the lung was well collapsed at the time. Lantern slides were shown of various stages of pulmonary collapse, with and without pleuritic effusion, and temperature charts of two acutely febrile patients both of whom had been restored to active life. Two patients were shown: in one the treatment had been completed and the lung allowed to expand, the last refill having been given seven-

teen months ago; the other patient was acutely febrile, but had done well in the second year of treatment.

Dr. NEVILLE COX said that pneumothorax treatment was constantly in the mind of those who, as tuberculosis officers, were handling large numbers of cases of phthisis. The difficulty was in defining the suitable cases. Definite evidence of breaking-down lung, as shown by elastic fibres in the sputum, was one indication. On the one hand, collapse treatment should not be started without adequate trial of other methods, and, on the other hand, deferring the treatment too long might lessen the chance of success. There was scope for much caution also during the conduct of the treatment, in deciding the intervals for refills, the pleural pressures suitable to the individual case, and in particular in guiding the patient safely through the common period of "pleural reaction," when it might be advisable to avoid refills for the time being. Stopping the treatment and allowing the lung to re-expand provided another difficult problem; there were probably many cases in which it was best to continue the refills indefinitely. No sensational figures of successful results were to be expected, but in view of the otherwise hopeless outlook of most of these patients, even a small percentage of permanently good results justified the treatment; in a large number of other patients added years of useful life, relief from unpleasant symptoms, and lessened infectivity followed pneumothorax treatment. Dr. Cox thought that there were still a large number of patients dying annually in this country who might have been helped by its timely adoption. As a contrast between the policy of *laissez-faire* and of active intervention in advanced phthisis, he instanced a remarkable case published in Gravesen's book on the surgical treatment of pulmonary tuberculosis.

Mr. M. FITZMAURICE-KELLY advocated the division of the adhesions by extrapleural thoracoplasty in those cases in which adhesions prevented the production of an artificial pneumothorax.

RICKETS.

At the annual meeting of the Devon and Exeter Medico-Chirurgical Society on January 21st, the retiring president, Dr. E. J. TOYE, in the chair, Dr. C. MILLER read a paper on rickets.

Dr. Miller began by saying that rickets afforded an example of intelligent empiricism, in that a satisfactory remedy had been discovered before the etiology and pathology of the morbid process had been established. Another interesting point was that the same remedy had a prophylactic, as well as a curative, action. Rickets had already become a sociological, rather than a medical, responsibility, but it was the duty of the medical practitioner to play his part in influencing public bodies with regard to better provision of houses and of food. Dr. Miller then gave a comprehensive account of the distribution, incidence, and pathology of the disease, emphasizing the importance of the slack hypotonic condition of the muscles as one of its earliest symptoms. Rickets was not solely a disease of ossification; it should be described rather as a fault in the metabolism of calcium and phosphorus, the effects of which were widespread in the body and not limited to infancy. The nervous instability of the rickety child was often continued into adult life. Dr. Miller described the historical study of the disease since Glisson's monograph in 1650, and Pommer's pathological study published in 1885. Rickets was probably non-existent in ancient times, or at the most was very infrequent and sporadic. The lecturer concluded with an account of the modern treatment by sunlight, improvement of environment, and the use of fats.

The CHAIRMAN raised the question of the incidence of rickets in breast-fed children, which appeared in his experience to be equal to that noted in those reared on artificial foods. It was rarely that they met with severe cases in the rural districts, but in the treatment of all types of cases he had obtained excellent results from the ultra-violet rays, although, unfortunately, the deformities still persisted at the end of treatment. He was a great believer in instructing the public in the elements of vitamin therapy and its special importance to infant life.

Mr. A. L. CANDLER quoted from a paper read by Sir J. Bland-Sutton, where it was mentioned that the earliest primitive life was domiciled in surface water; humanity was still primitive enough to need light. He discussed the cod-liver oil value in the treatment of rickets, and raised the question as to the source of the vitamins in the oil. He suggested that the more primitive organisms of the ocean were the probable manufacturers of the vitamins.

Dr. COHEN had found ultra-violet rays beneficial in the treatment of coeliac disease. He also alluded to experiments on rats living in a cage spread with sawdust which had been previously treated with ultra-violet rays; although the rats were kept in the dark rickets did not occur amongst them.

Drs. R. V. SOLLY, PEREIRA GRAY, A. HIPWELL, FOULKES, and Mr. WATLAND SMITH also contributed to the discussion.

Dr. MILLER in his reply stated that medical research had shown that lack of breast-feeding was not a factor in the causation of rickets provided that artificial feeding was carefully chosen as regards the composition of the food. He also mentioned the advantages of certain patent infant foods over others, but hoped for the day when they would be unnecessary. At the moment it could be claimed that they were microbe-free, which could not be said for the "white sewage" so often placed on the market as milk. It was just possible that breast-fed children could acquire rickets if sunlight was deficient. Experiments had shown that mother rats kept under the most favourable conditions as regards exercise, sunlight, and feeding became antirachitic, and were capable of passing on this protection to the children of the third generation. These properties were not, however, found, so far as was known, in human milk, although they might be expected to occur rather in the countries of the East than in Northern Europe. As regards the pathology of coeliac disease they were still in the dark. The prominent feature was the inability to digest fats, and various organisms had been claimed as the specific causal agents, notably the Flexner bacillus. Artificial feeding undoubtedly predisposed to the disease, and most of the cases had occurred amongst artificially fed children, but beyond this information was scanty. Generally speaking they should advocate natural food, sensible clothing—and not too much of it—with a maximum of outdoor life, and aim at getting back to nature.

VAGINAL BACTERIOLOGY.

At a meeting of the Section of Pathology of the Royal Academy of Medicine in Ireland on January 8th, the President, Professor J. W. BIGGER, in the chair, Dr. MARY M. MERRICK read a paper on the bacteriological findings in vaginal discharges, based on a joint investigation with Dr. DOROTHY H. DOUGLAS in the Coombe Hospital, Dublin.

Dr. Merrick said that the standard classification of Heuslin had been adopted in studying the vaginal flora in these cases. There was reason to believe that the vaginal lactic acid bacilli were not specific micro-organisms, but involution forms of *B. coli*. The importance of the lactic acid bacilli in maintaining the normal acid reaction of vaginal secretion was discussed. Vaginal discharge, when not due to such common causes as erosion, laceration, gonorrhoea, and post-gonorrhoeal catarrh, was possibly due to psychogenic impulses passing from the brain to the glands of the cervix; hence this type of discharge was frequently associated with mental disturbances and emotions. Deep x-ray therapy was used with success in cases due to hypo-ovarian conditions. While bacteriological examination was helpful in tracing the source and cause of a persistent vaginal discharge, there were many difficulties and fallacies to be remembered. A simple Gram-stained preparation had given more information than cultures, which had produced growths of staphylococci with discouraging regularity. Several cases were described, with the bacteriological findings, diagnosis, treatment, and results.

The PRESIDENT said that he had examined for gonococci a very large number of films prepared in a female venereal dispensary, and had been struck by the large number of bacteria he had found; the number of other Gram-negative diplococci was much larger than the number of gonococci,

and these were never found in pus cells. He doubted whether freedom from disease was indicated by the vaginal discharge being acid; he believed that the acidity was due to the vagina being healthy, but if the reaction at birth was acid it was apparently kept acid by some organisms. A vaginal discharge might be due to a great many different organisms, but yet in some cases it was only due to one organism. He had recently seen a specimen of vaginal discharge which had only appeared to contain Gram-negative bacilli; in such cases as this there was apparently only a single infection. He referred to the presence of spirochaetes in the vaginal discharge, and said that he thought these were fairly common in the external genitals in both sexes. To discover the presence of pneumococci in the vagina was not at all easy; the only method was to isolate the organism in pure culture.

Dr. J. LAIT asked if it was possible to diagnose hypo-ovarian conditions from the exogenous discharge. Pregnancy was a hypo-ovarian condition, and in pregnancy one would expect to find diminished glycogen, yet an increased acid reaction was found in pregnancy.

Dr. D. J. CANNON referred to cases in which the gonococcus was not present, and there was laceration of the cervix; he said that, as a rule, these cases were very puzzling, as it was difficult to know where the infection came from. If this discharge was examined, a few micro-organisms were found, and he believed that the infection was caused by the micro-organisms in the vagina getting the upper hand, and causing a discharge. In cases of chronic vaginal discharge it was always difficult to diagnose gonorrhoea, unless the patient gave a definite history. Backward displacement of the uterus could, in his opinion, cause so-called non-infective leucorrhoea. If there was a pathological discharge from the cervix, and backward displacement of the uterus, operative correction of the displacement would not stop the discharge.

Dr. R. H. MICKS remarked that it would be interesting to find out how often (if ever) pneumococci were found in the normal vagina, and if pneumococci were present in any vaginal discharges. Dr. W. D. O'KELLY thought that the possibility of the conversion of Gram-negative into Gram-positive bacilli could not be admitted.

HYOSPADIAS.

At a meeting of the Section of Anatomy and Physiology of the Royal Academy of Medicine in Ireland on January 22nd, the President, Dr. C. M. WEST, in the chair, reported a case of hyospadias.

Dr. West said that the specimen exhibited consisted of the contents of the sac of an inguinal hernia which had been sent to the anatomical department in Trinity College by Mr. Seton Pringle. An unmarried woman, aged 38, was admitted to hospital for inguinal hernia. She had considerable growth of hair on the face, and the masculine type of breasts, pubic hair, and limbs. She had never menstruated, but had had some bleeding from the external genitals once, about two years ago. Dr. West showed lantern slides of the external genitalia, which consisted of a small penis and a large canal behind it, about the length of an index finger. The canal had the appearance of a vagina, and was guarded by two folds which resembled labia minora. The sac of the hernia contained a fairly large, tortuous, and pyriform body, the epididymis, and a very small spherical structure which appeared to be the testis; there was a large and normal-looking vas deferens, and no evidence of any ovarian tissue. Dr. West suggested that the patient was really a male, in whom the lips of the urethral groove had failed to fuse, thus giving rise to the folds which resembled the labia minora, and that the lower part of the embryonic urogenital sinus had formed the vagina-like canal.

Dr. W. A. TAYLOR drew attention to the large quantity of male genital tissue found in the hernial sac, and asked if the vas went up normally into the inguinal canal.

The PRESIDENT, replying, said that there was no connexion between the vas and the epididymis. The patient had once had a discharge from the neighbourhood of the external genitals, two years before, but that was the only sign of menstruation.

Reviews.

ALLERGIC DISEASES, INCLUDING ASTHMA.

DR. W. STORM VAN LEEUWEN, Director of the Pharmacotherapeutic Institute at Leyden, has brought out a work valuable for its independence and for its basis of much observation and thought—*Allergic Diseases: Diagnosis and Treatment of Bronchial Asthma, Hay Fever, and other Allergic Diseases*.¹ His references cover a wide field of recent writers, especially American workers, but there is not any notice of John Bostock, who described hay fever in 1819, or of Hyde Salter, whose conceptions must be considered quite modern. Stimulated by a visit in 1919 to the clinic of Dr. Chandler Walker of Boston and by his results with skin tests as a guide to specific treatment, the author fully investigated this diagnostic method, but has arrived at very different, indeed rather revolutionary, conclusions. Thus he finds that in the majority of asthmatic patients the real causal agent cannot be found; that skin tests give multiple positive results in the same patient in a large number of cases; 37 per cent. of his patients reacted to more than ten extracts, 14.5 per cent. to from five to nine extracts, and 26 per cent. to from two to five extracts; nearly all asthmatics, he says, show positive results with horse dandruff, whereas normal persons hardly ever do. He therefore thinks that the real value of skin tests is to enable an allergic patient to be recognized, and that they cannot be relied on to indicate the specific agent or allergen. Sensitization to animal proteins is regarded as rare in asthma, and it is asserted that the nature and chemical composition of very active extracts made from protein substances, such as meat, white of egg, and dandruff, is unknown, and that in some extracts of this kind no trace of protein can be found. The question of whether or not allergic diseases are due to anaphylaxis and the distinction drawn between these two conditions are discussed with impartiality. One of the main factors in the etiology of allergic diseases is considered to be increased permeability or vulnerability of the skin and mucous membranes, which allows allergens to pass in; 50 per cent. of the author's asthmatic patients had eczema of the face in childhood, 30 per cent. had previously suffered from bronchitis, and of the remaining 20 per cent. some had passed through a disease, such as typhoid or a gastric ulcer, during which the intestinal wall is more permeable. The responsible agent may be toxic and an irritant, so that it may set up inflammation at the start, or it may be a pure allergen—that is, active after sensitization only. The author believes that allergic diseases are largely due to inhalation of the products of fungi and yeasts in the air, and urges the well known influence of places and the absence of asthma in the pure air of high altitudes as arguments in favour of this view. The therapeutic use of pure air chambers has given very good results, and patients can have such chambers built on to their bedrooms so as to employ the treatment at home. As regards the treatment of allergic disease the author argues that, as the real cause is rarely ascertainable, the treatment must usually be non-specific, and that some supposedly specific forms of treatment are not really of that nature. Among the various non-specific methods tuberculin is described as having proved successful in his hands, about half his three hundred patients being completely, or almost completely, cured. Written in good English and well argued, this monograph deserves consideration.

Many remarkable examples of hypersensitiveness are described by Dr. W. W. DUKE in his book *Allergy: Asthma, Hay Fever, Urticaria, and Allied Manifestations of Reaction*.² He uses the term "allergy" in a very broad sense; he begins with a description of experimental anaphylaxis, serum sickness, and bacterial allergy, and goes

on to discuss sensitiveness to various animal and vegetable products. Pollen receives a very detailed botanical treatment, and these pages of the book are illustrated with excellent photographs of the plants and the seeds. We begin to wonder whither we are being led in the ninth chapter, on primary causes of reaction other than pollen, for the author discusses the question of one human being becoming sensitive to another, and people becoming sensitive even to themselves. But it must be admitted that, though some of the cases cited sound most unusual, the painstaking and elaborate investigations undertaken seem to justify the diagnosis in most cases, though the cautious reader may be sceptical about others. The second part of the book treats of reactions caused specifically by physical agents, such as light, heat, cold, mechanical irritation, freezing, and burns. The author speaks also of reactions brought about indirectly by the effect of mental or physical effort. Reactions caused by physical agents, he maintains, fall into two distinct classes: first, those in which the reaction is confined to the area directly exposed to the physical agent; and secondly, those in which the reaction is widespread and affects not only areas directly exposed but distant tissues as well. The former type he speaks of as "contact reactions," and the latter as "reflex-like reactions." A series of striking photographs accompany the descriptions of the idiosyncrasies he designates as "urticaria solaris," "urticaria hiemalis," and "urticaria demographica." This is dealt with entirely from the clinical point of view. There is, of course, a theoretical side to this question of allergy, which is one of the most intricate problems immunologists have had to face. Dr. Duke does not exhaust the reader by trying to lead him through fields of speculation. Since this is essentially a practical book, he very wisely contents himself with quotations from standard textbooks on chemical pathology and immunology when theoretical explanations or enlargements are necessary.

MALIGNANT DISEASE OF THE TESTICLE.

THE honour conferred on Mr. HAROLD R. DEW for his essay on *Malignant Disease of the Testicle*³ by the award of the Jacksonian prize in 1923 was well merited, for it is a welcome addition to the literature of the subject. The condition is extremely rare, and there has been a good deal of confusion, and what many of the surgical textbooks have to say about it is out of date or even erroneous. The curious and complex nature of testicular tumours has long interested pathologists and surgeons, and Mr. Dew has brought together all the recent knowledge. Although he has based his work on the study of forty hitherto unreported cases, he has delved widely into the literature, and acknowledges a debt to the French observers for much of the knowledge which exists on the pathology, the clinical aspects, and the treatment of these neoplasms. The book is uncommonly well illustrated, containing five coloured plates and a number of sketches, photographs, and microphotographs, the majority from original specimens. After dealing with the anatomy and development, the writer discusses the morbid anatomy and histology from an historical point of view to show how the confusion in classification has arisen. His own classification is based mostly on the histogenetic aspect; three main groups are recognized—the teratomata, the carcinomata (seminomata), which are almost equally common, and the sarcomata, which comprise only 1 to 2 per cent. of malignant testicular growths. Many carcinomata, he considers, have been wrongly classified as sarcomata; they arise in the seminal epithelium. Compared with the teratomata they are less malignant and metastasize later. Tumours of each group obey the laws of their respective classes as regards malignancy, metastases, and recurrence. With regard to the etiology, the author considers trauma has a definite causal relationship; that the incidence of malignancy in an ectopic testis has been exaggerated; and that there seems to be no relation between inflammatory processes and tumour formation.

² *Allergy: Asthma, Hay Fever, Urticaria, and Allied Manifestations of Reaction.* By William W. Duke, Ph.D., M.D. London: H. Kimpton. 1925. (Med. 8vo, pp. 332; 75 figures. 25s. net.)

³ *Malignant Disease of the Testicle. Its Pathology, Diagnosis, and Treatment.* By Harold R. Dew, M.B., B.S., M.D., F.R.C.S. Eng., F.A.C.S. London: H. K. Lewis and Co., Ltd. 1925. (Roy. 8vo, pp. 168; 52 figures, 5 coloured plates. 21s. net.)

Teratomata tend to occur early, between 20 and 30, and the carcinomata a decade later. The clinical types are classified under three headings: (1) cases in which the disease is confined to the scrotum; (2) advanced cases with extension; (3) neoplastic changes in an abnormally placed testis. In all doubtful cases of testicular enlargement early exploratory incision should be regarded as the indispensable and final means of diagnosis.

In discussing treatment a strong plea is made for early radical operation. The results from simple orchidectomy are so bad that the radical operation, although a severe one, ought to be performed, provided there are no contraindications. Early exploratory incision, followed by removal of the glandular area of drainage, offer the most hopeful results.

Mr. Harold Dew is to be highly complimented on the way in which he has presented his subject. It is from such superficial organs as the testis that the problem of malignancy can best be studied, and although we are as yet far from discovering the factors of its causation this book shows the tenacity with which the subject is being pursued. From its rarity, its complicated cellular composition, its extreme malignancy, and the difficulty of treatment, the testis more than any organ merits this attention. If we may make one criticism, it would be that Mr. Dew had not made a comparative study and included in his work malignant disease of the testis which occurs in the horse and other lower animals.

STUDIES IN NORMAL PSYCHOLOGY.

IN a volume entitled *Behaviorism*¹ Dr. JOHN B. WATSON gives a further exposition of his psychological doctrines which have been the subject of so much controversy. The book consists of a series of twelve lectures and covers much the same ground as the author's textbook of 1919, though it is written in a more popular style. It also includes an account of his latest work on the congenital and acquired responses of children ranging in age from a few months to 7 years. These researches are of considerable interest and importance, and should be taken into account in any future discussions on the nature of the emotions and instincts. Dr. Watson is a clear and courageous writer, and he is evidently intent on arriving at the facts about human nature. He has certainly something of value to teach, though we feel that his views would carry more weight if they were expressed with more restraint and in a manner less reminiscent of political propaganda.

Mr. J. L. BERNARD, Professor of Sociology, University of Minnesota, in a scholarly book on *Instinct: A Study in Social Psychology*² arrives by a different route at conclusions similar to those of Dr. Watson as to the paramount influence of environment in the determination of human behaviour and in the formation of character. In his opinion the biologist and psychologist have laid far too much stress upon the instinctive factors in conduct. His investigations lead him to the view that the environment increasingly dominates both the content and the direction of habit formation. He considers, therefore, that it is from the standpoint of the content and the organization of the psycho-social environment that the study of the control of the growth of human character should be approached, the instincts being regarded primarily as the original—not necessarily the immediate or the only—starting-points in the process. The future control of the human race, he holds, lies, not through selective breeding of the higher social qualities—although selective breeding of those traits which can be so bred is of the greatest importance—but through their transmission by social contact and control. Much of the book is taken up with critical discussions on the various theories and conceptions of instinct.

Miss HELGA ENG is responsible for interesting *Experimental Investigations into the Emotional Life of the Child*,

compared with that of the Adult.³ The apparatus selected for carrying out these researches was the plethysmograph, as the method had proved in former experiments to be the best adapted for the purpose. Special interest is attached to Miss Eng's observations on the "spontaneous curves" occurring during the course of her experiments. Other investigators have noted these curves, but appear to have seen in them merely disturbing factors in the experiment, rather than a profitable field of investigation. Actually they were due to spontaneous psychical activities occurring independently of any stimulus arranged by the experimenter. Thus evidences of emotional disturbance, either pleasurable or the opposite, were found to result from such factors as thoughts of ski-ing, anticipated birthday presents, castor oil, a bad dream, or a dead brother; or were perhaps due to the contemplation of a blouse or a depressing shadow. Such data afford some insight into the influence of underlying emotional factors upon the reaction of an individual to the daily tasks of life. In concluding her book the writer says that while Mosso came to the conclusion that the psyche in all circumstances appears to be the slave of matter, for her part she finds the strongest reasons to reverse that view, and to say that there is nothing to which matter is more subservient than mind.

FRENCH VIEWS ON PULMONARY TUBERCULOSIS.

THE second edition⁴ of Dr. LÉON BERNARD's book on pulmonary tuberculosis is not only larger than the first, which was sold out in three years, but is in many respects altered and improved. Fresh chapters have been added, recent acquisitions to our knowledge inserted, and a clearer conception worked out of several points that were previously ill defined. Though the author is essentially a product of the French school, he does not carry his ideas to the degree of exclusivism that is so annoying in some of his compatriots. It is true that he has been rebuked by the Americans for neglecting to take notice of their work, but, as he states in his preface, he did not set out to write a treatise, but rather to make a contribution of his own opinions, founded on the investigations of himself and of his pupils. In this he has been successful.

It is in this type of work that the French show themselves to advantage. The clear-cut ideas, the dogmatic assertions, and the lucid style render their books eminently readable, and suitable for the practitioners for whom they are intended. No one with a knowledge of scientific literature would go to the French if what he desired was a general review and critical discussion of the present position of an obscure subject. He would be disappointed. All that he would find would be a summary of the French point of view. It is for this reason—their neglect of the work of other nations—that the French are so far behind their English and American contemporaries in their systematic treatises and monographs. But in a book such as Léon Bernard's this failing is of no importance. We think, in fact, that he has chosen the right method for productions of this type in limiting himself to the exposition of ideas rather than to their discussion.

For English readers the most interesting chapter will undoubtedly be that devoted to the social prevention of tuberculosis, in which he not only describes the various methods of combating the disease, but brings evidence of their success. It is pleasing to find an authority on tuberculosis who is not a fanatic, who does not pin all his faith to the dispensary, to the sanatorium, or to the village scheme of settlement. Each of these methods is of value, and the author brings out clearly that all are required and that all are useful, provided the integration between them is perfected. We have no hesitation in recommending this volume to tuberculosis officers in particular, and to general practitioners who still doubt the value of present methods of prophylaxis.

SCIENCE, RELIGION, AND REALITY.

THE object of the book *Science, Religion, and Reality*,^{*} edited by Mr. JOSEPH NEEDHAM, is to make clear what are the present relations between science and Christianity. The book is not directly apologetic in its tone; it is neither a defence nor a criticism of Christianity. It does not attempt to patch up past quarrels, or secure reconciliation by compromise, but simply records the opinions of nine well known scientists and philosophers, each of whom writes about his own particular subject. The book is therefore intended to be a mirror of contemporary scientific thought about religion.

Two medical men have contributed to this discussion—Dr. Charles Singer and Dr. William Brown. Dr. Singer, as was to be expected, has written on the historical relations of religion and science; he has carried his review down to the period which he terms the reign of law, a period ushered in by the extraordinary wealth of scientific discovery with which the seventeenth century opened; a wealth crowned by the work of Newton. The record of the relations between science and religion in the nineteenth century has been left to Dr. Antonio Aliotta, Professor of Philosophy in the University of Naples. Dr. William Brown, Wilde Reader in Mental Philosophy at Oxford, has written an article about religion and psychology which will interest many medical readers because of his skilful analysis of the relation which suggestion, faith, and mysticism bear to the everyday working of the mind. Mr. Joseph Needham, the editor of the book, has written from the point of view of a physiologist on the subject of mechanistic biology and the religious consciousness. Every biochemist and biophysicist must, he thinks, be a thorough-going mechanist, but this attitude need not be incompatible with religious convictions. One of the most readable and also most provocative contributions is that by the distinguished astronomer, Professor Arthur Eddington of Cambridge, who has written on the domain of physical science. He makes a delightful beginning in his comparison between the point of view of the learned physicist and that of the man in the street. Another interesting portion of Dr. Eddington's article is that in which he writes of the relation between Einstein's theory of relativity and religious doctrines. The scientific conception of the universe which the modern physicist has built up seems likely to modify religious doctrines even more than the biologists did with their theories of evolution in the last century. We must mention also Dr. Malinowski's essay on magic science and religion, which has, of course, special interest for the anthropologist. In his concluding article Dr. Inge does not attempt to harmonize the widely different views expressed by the other writers, but comments on what he considers to be the main ideas of his collaborators.

ANNALS OF MEDICAL HISTORY.

THE winter or last number of volume vii of the *Annals of Medical History*⁹ opens with a carefully documented account, by Major E. E. Hume, of the life and work, particularly on the theory of the etiology of cholera, typhoid fever, and other intestinal diseases, of Max von Pettenkofer (1818-1901), whose rugged features appear on the cover. Though his logic was not always of the best, he had the courage of his convictions, as proved by his swallowing in 1892 a culture of the cholera bacillus; in addition there is for the first time a complete list of his 228 publications. A fine portrait of Sir Dominic Corrigan forms the frontispiece, and Dr. R. T. Williamson describes the life and work of that famous Dublin physician, who took the M.D. Edin. in 1825. In addition to his well known descriptions of aortic reflux and chronic interstitial pneumonia, he wrote "On aortitis, as one of the causes of angina pectoris," which even Sir Clifford Allbutt, who had independently and on broader lines contended for the

aortic origin of angina, had not any knowledge of until some six months after the delivery of his well known lecture on the subject in 1907. Dr. Stephen D'Irsay writes on the life and works of Gilles de Corbeil or Aegidius Corboliensis, born about the middle of the twelfth century, who was educated at Salerno when at the zenith of its reputation and carried its teaching to Paris, where he was archiater or physician-in-ordinary to King Philip Augustus, and wrote textbooks which, though not original, maintained for three hundred years the Salernitan tradition. The influence on medical progress of the work of Carl Rokitansky (1804-1878), the founder of the so-called Austrian medico-anatomical school which made Vienna the centre of medical learning, is sketched by Dr. F. R. Menne, who regards him as probably the greatest single balancing force in medical science of the nineteenth century. The medical wisdom of Mark Twain, who for years bore the burden of chronic bronchial colds and rheumatism and died in his seventy-fourth year from angina pectoris, is analysed by Dr. L. J. Bragman. The second and concluding part of Frances Long Taylor's life of her father, Crawford Williamson Long, who in 1842 initiated surgical anaesthesia by ether, is an interesting addition to the history of the subject. Dr. W. G. Aitchison Robertson contributes an article on "The powder of sympathy," which has been stated to have come from the East, but might almost have been evolved from the inner consciousness of one of the witches in *Macbeth*, to judge from its horrible constituents; it, however, was advocated for the cure of wounds, not only by Sir Kenelm Digby, but by Nathaniel Highmore, the anatomist. Dr. F. H. Garrison renders from the original German into graceful English verse the only poem in praise of ophthalmologists that he has found in the numerous efforts in praise of our profession which he has patiently perused.

NOTES ON BOOKS.

The Art of Vicarious Prescribing.

AT some period in the development of the art of medicine there must have existed adventurous spirits who experimented in the mixing of drugs to form a prescription. Nowadays the young practitioner is saved much trouble in that he can always have at hand a book of other people's formulae. Thus, Dr. ESPINE WARD sets forth his *Favourite Prescriptions*,¹⁰ culled from various standard textbooks, some with modifications that he has found of value. Dr. Ward disarms criticism by prefixing to his book the cynical little motto: "For many patients hope is the best medicine." The book is divided into three sections: dosage tables, hints for treatment of poisoning, and prescriptions. The prescriptions are arranged under an alphabetical list of diseases, which in one direction is so complete as to contain an aphrodisiac, while in the other direction it fails to include syphilis, except on the preventive side in the matter of a prophylactic ointment.

A work of more solid value is the eleventh edition of *The Book of Prescriptions*¹¹ by Messrs. E. W. LUCAS and H. B. STEVENS. The first edition was published in 1856. Drugs are described in alphabetical order, with notes on their pharmacology and therapeutics. At the end of the description of the more important drugs prescriptions are given, with a statement of the diseases for which each is appropriate. An index of diseases and remedies completes the volume, which should be of value to both practitioners and students.

*Principal Drugs and their Uses*¹² is a little handbook intended to convey information to nurses. Each page consists of three columns: the name of the drug, its nature, and its use. The contents of the second column are not highly illuminating; nor are they based on any definite scheme of illustration. The nature of acetyl-salicylic acid is that it is "prepared from salicylic acid"; the nature of aspirin is that it is "the trade name of a synthetic compound"; the nature of beeswax is that it is "a secretion of the bee." Under the heading "Uses" also the information seems defective. Thus of thyroid gland it is said, "prescribed in obesity, goitre, and psoriasis."

British Medical Journal.

SATURDAY, FEBRUARY 13TH, 1926.

EPIDEMIC DISEASES OF THE NERVOUS SYSTEM.

THE four infective diseases of the central nervous system—poliomyelitis, polioencephalitis, cerebro-spinal fever, and encephalitis lethargica—when considered from the epidemiological point of view, are found to show certain very characteristic differences. The seasonal behaviour of these infective diseases is distinctive, and year after year each maintains its traditional habit. Cerebro-spinal fever shows preference for the winter and spring months of the year. Acute poliomyelitis and polioencephalitis remain essentially diseases of late summer and autumn. On the other hand, encephalitis lethargica is commonest usually in the first quarter of the year, though it happened that in 1924 the heaviest incidence took place in the second and not the first quarter. This seasonal distribution holds good for all countries in northern latitudes, but south of the equator conditions are reversed, and in Australia poliomyelitis is a disease of the first half of the year and encephalitis lethargica of the third and fourth quarters. Knowledge gained from a consideration of the seasonal behaviour of these diseases may at times have important clinical value, as Dr. A. K. Chalmers, the medical officer of health for Glasgow, pointed out recently in the Watsonian Lectures delivered before the Royal Faculty of Physicians and Surgeons of that city. When encephalitis lethargica occurred in the spring of 1918 there was a disposition in some quarters to regard polioencephalitis as a clinical variant of that disease rather than of poliomyelitis, but the seasonal distribution, corresponding as it does with the latter, tended to clear up the doubt. Dr. Chalmers has shown also that in Scotland the epidemic diseases of the central nervous system differ in age and sex distribution in a remarkable fashion. It need hardly be mentioned also that they differ radically in their sequelae.

It is usually assumed that all these diseases are spread by contact from case to case or by the agency of a healthy "carrier." This has, of course, been clearly established for cerebro-spinal fever, and it has been shown that the "carrier rate" among troops increased according to the dangerous degree of overcrowding in barracks. With encephalitis lethargica, however, case-to-case infection can rarely be traced, and the solitary instance which occurred during 1923 may be mentioned only as a curiosity. In a family at Eastbourne three brothers and a sister, all of school-going age, were attacked, one after the other, with encephalitis lethargica in July, 1923. The sharp outbreaks of encephalitis which occurred in Glasgow in 1923 and 1924 followed a very capricious distribution, as is shown by the map of Glasgow in which the distribution of this disease during these epidemics is plotted. Dr. Chalmers noted that few cases had more than a topographical association, but on one occasion two cases arose in different households in one tenement within a week of each other. The one- and two-apartment population, where pressure on house-room is greatest, had an almost similar attack rate—41 and 44 respectively per 100,000; among the population dwelling in three and four rooms it fell to 34 and 19, and only 13 cases occurred in institutions. In view of such facts as these the ordinary carrier theory, though

convenient as a working hypothesis, needs critical consideration from time to time. Dr. Chalmers remarks that such experience as we have of plague in this country might have been used to illustrate the same theory, had we not known of the part played by the rat and its parasite.

On the connexion between sporadic cases of cerebro-spinal fever and epidemic prevalence the medical officer of health for Glasgow has some interesting comments to make. No doubt the sporadic case is the slender thread which links one outbreak with another, but there is good reason to believe that this sporadic case eludes detection during the non-epidemic period. An analysis of the records of deaths from other forms of meningitis in Scotland during the years which preceded the epidemic of 1906 seems to reveal a steady transference of deaths from "meningitis" to tuberculous meningitis, and then to cerebro-spinal fever. As highly suggestive of the possibility that in the pre-epidemic period cases of cerebro-spinal fever were being notified as tuberculous meningitis, it may be mentioned that there is no other evidence to prove that any form of tuberculosis was increasing in these years. It would appear, therefore, that the sporadic case keeps up the association between epidemics, under the guise of meningitis arising from other causes, and then at intervals takes on the more obvious features which are recognized as an epidemic.

Reflections such as these open up the question of the need for a more widespread notification of diseases of the nervous system. Many observers hold that the present phase of cerebro-spinal fever has much in common with the period which formed a prelude to the explosive outbreaks on the Continent during last century. Whether this be so or not, there is much to be said for the additional notification of those other forms of meningitis which experience has shown may in reality be unrecognized cases of cerebro-spinal fever.

VARIOLA RESEARCH.

IN to-day's issue (p. 299) we publish notes of a conference held last month under the Health Committee of the League of Nations regarding questions connected with small-pox, mild and severe in type, and with vaccinia. The conference arrived at conclusions of the highest importance in respect of intensive international research into every problem relating to variolous disease and its control. Perusal of the draft scheme of investigation submitted by the president of the conference, Professor Ricardo Jorge, indicates how all-embracing are the questions propounded for consideration. At the same time the circumstances are peculiarly suitable for the inquiry, both from the executive and the scientific point of view. The increasing prevalence in recent years of a much modified variety of small-pox in various parts of the world, interspersed with occasional outbreaks of the classical or severe type of the infection, gives a wide interest to the subject, at the same time that the Health Organization of the League makes practicable an investigation on the completest scale, bringing under review every relevant fact belonging to every individual country. Furthermore, advances in the sciences relating to the causes and control of infectious disease, by immunization and otherwise, have been so rapid in recent years that the application of newer knowledge to questions of prevention and control should be of the utmost advantage in reaching conclusions and making recommendations.

The draft scheme submitted by Professor Jorge is in two parts, epidemiological and experimental, but is

so inclusive and far-reaching that the conference, doubtless in view of the time involved, has selected three lines for first consideration. These are briefly (1) to pursue the study of mild small-pox (for which the name "alastrim" has been needlessly adopted in the report) as fully as possible, both clinically and epidemiologically; (2) to form conclusions from inquiry at vaccine institutes as to the essential matters over which Government control should be exercised, and to compare recently proposed tests for measuring the potency of vaccine lymph; and (3) to give close attention to the affection of the nervous system reported to have followed vaccination in some countries. On this last subject it is advised that various Governments be asked to collect information from their public health authorities. The commission will report on all the data thus obtained, while technical investigations are being carried out by experts.

As anticipated in our last issue (p. 256), the announcement is now made that in this country the Minister of Health, acting in conjunction with the Medical Research Council, has appointed a strong committee to share in the inquiry. The committee's terms of reference are "to inquire and report from time to time (1) on matters relating to the preparation, testing, and standardization of vaccine lymph; (2) on the practical methods which are available in the light of modern knowledge to diminish or remove any risks which may result from vaccination; (3) on the methods of vaccination which are most appropriate to give protection against risk of small-pox infection in epidemic and non-epidemic periods; and to co-ordinate the work of investigation on these questions in this country and abroad, having regard to corresponding work undertaken by international health organizations." The chairman of the committee is Sir Humphry Rolleston, Bt., Regius Professor of Physics at Cambridge and President of the Royal College of Physicians of London. The other members are Dr. F. R. Blaxall, bacteriologist to the vaccine department of the Ministry of Health; Dr. G. F. Buchan, medical officer of health for Willesden; Dr. A. E. Cope, teacher in vaccination under the Ministry and honorary secretary of the Association of Public Vaccinators; Dr. Mervyn H. Gordon, F.R.S., consulting bacteriologist to St. Bartholomew's Hospital; Dr. J. C. G. Ledingham, F.R.S., professor of bacteriology in the University of London and chief bacteriologist at the Lister Institute; and Dr. J. R. Perdrau, pathologist to the Lambeth Hospital. The secretary is Dr. J. R. Hutchinson, a medical officer of the Ministry of Health, Whitehall, S.W.1, to whom all communications relating to the work of the Vaccination Committee should be addressed.

The results of the committee's labours will be awaited with keen interest by all who are concerned with the prevalence and prevention of variolous disease, both in this country and abroad.

MEDICAL PARASITOLOGY.

THE enhanced position given to the subject of medical parasitology is one of the most suggestive of several notable changes effected by the General Medical Council in the revision of the curriculum for the Diploma in Public Health. This is due recognition of the fact that several very prevalent and fatal diseases, more especially of tropical countries, have been shown in recent years to be caused by protozoal and helminth parasites, and that the elucidation of their life-histories has provided the hygienist with the means of eradicating these diseases. These investiga-

tions were carried out in very adverse circumstances, often far from sources of scientific literature, with meagre equipment and long before the highly elaborate technique considered necessary to-day had been evolved. It is inspiring to think that many of the pioneers were men of our own country and profession. These early workers deliberately, as well as of necessity, focused their attention upon the pathogenic parasites of man. The instinct of genius undoubtedly guided their untrained steps, for it is remarkable how many pitfalls were avoided and how many were the successes gained in a field so unsuspectedly full of difficulties and complications. The parasitologist of to-day must be acquainted with the morphology of the pathogenic and commensal organisms in man. He must also know and be ever on the lookout for contaminations with free-living forms and for congeners in other hosts. Particularly must he keep in mind the parasites of those hosts which serve as human food, for these allied forms may passively traverse the human intestine to appear in the faeces, not as living parasites or commensals of man, but merely as inert foreign bodies. Disaster awaits the microscopist who fails to realize adequately that the bulk of human excrement has entered the body as food. Lately Sandground (1923) showed that *Oxyuris incognita*—a worm reputed to have infested hundreds of American recruits during the late war—is merely a nematode infesting food vegetables. In our present issue (p. 282) Drs. J. G. Thomson and A. Robertson of the London School of Hygiene and Tropical Medicine show that a number of recently described coccidia in man are merely known species passing through the intestine after a meal of herrings or sprats. Since their paper was put into type for the press we have learnt that one of these species—namely, *Eimeria oxyphora* Dobell, 1919—occurs in tinned sardines from Portugal and in the soft roes of herring tinned in Norway. These organisms have remained quite distinct and readily recognizable, although they must have been subjected to a high temperature in the process of manufacture. It is evident that special skill and experience is needed to-day to assess aright the medical significance of parasitological findings. The tendency in America has been to hand over these studies to the specializing professional zoologist. In this country, however, authoritative opinion appears to favour the view that a previous medical training is as desirable for the medical parasitologist as for the bacteriologist. After all, the medical student nowadays acquires probably as broad a training in microscopical technique and interpretation as the young zoologist; and if medical parasitology is to take its place beside bacteriology as a distinct and essential branch of the profession, it is a wise policy to encourage medical men and women with an aptitude for zoological investigations to train for this work. In no other way can it be assured that the future association of the parasitologist, the clinician, and the hygienist will be one of real and mutual understanding.

DIPHTHERIA AND SCARLET FEVER.

THE diagnosis of diphtheria by bacteriological examination of throat swabs carries with it four serious risks. There is the usual but unwise delay in the administration of antitoxin while awaiting the result of the examination; in patients with "positive" swabs the bacilli are not always biologically diphtheria bacilli or virulent; the admission to hospital of such people with a diagnosis of diphtheria entails the risk of their contracting diphtheria in the ward; and there is also the possibility of segregating carriers of virulent bacilli in close contact with susceptible subjects who happen to have bacilli resembling the true diphtheria bacillus in their throats. We have at various times called attention to the

deficiencies of the ordinary practice of "swab diagnosis" in diphtheria, and Dr. R. A. O'Brien emphasized these points in a discussion before the Medical Officers of Schools Association which is reported at page 287 this week. In the course of his remarks Dr. O'Brien emphasized the value of the Schick test in preventing those undesirable results of uncontrolled swabbing, and argued with some force against the measures usually employed in a school for controlling an epidemic of diphtheria. Indiscriminate swabbing may result in incarcerating in the sanatorium "positive swab" children who happen to have innocent bacilli resembling the Klebs-Loeffler bacillus in their throats, in close contact with carriers of true and virulent diphtheria organisms. Such carriers are Schick-negative and immune to diphtheria, but the "swab-positive" child with bacilli merely resembling the true diphtheria bacillus may be Schick-positive, and therefore susceptible to bacilli spread by his neighbour, the virulent carrier. The administration of antitoxin to all the contacts cuts short the epidemic, and may be completely and finally successful; but it sometimes fails. Unless the cause of the epidemic is eliminated, the disease may recur in a few weeks when the immunity conferred by the diphtheria antitoxin has faded. The Schick test, according to Dr. O'Brien and his colleagues, enables firm control of the situation to be gained in twenty-four to forty-eight hours. Those who give a positive reaction are kept under careful observation, while from the throats of the negative reactors swabs are taken, if necessary on several occasions, until the medical officer is certain that no carrier of virulent organisms is at liberty to restart an epidemic. If active immunization is decided on, the "diphtheria simultaneous prophylactic and indicating mixture" (DPIM) recently described by Glenn¹, when perfected, may control the testing and immunization more satisfactorily than in the past and possibly shorten the whole process. Dr. O'Brien reported that Dr. E. R. Harries had made a small number of observations which suggested that by the intradermal injection of the prophylactic indicating mixture an approximation to the Schick test reaction was obtained, while immunizing effects were also produced. Immunization by the present methods was successful, and diphtheria was being rapidly abolished from among the staffs of fever hospitals.² The school medical officer is also concerned with scarlet fever; here the Dick and Schultz-Charlton tests give considerable help in diagnosis. Dr. O'Brien remarks that if a patient with a "suspicious" throat and early rash gives negative Dick and Schultz-Charlton reactions the disease is almost certainly not scarlet fever. Antitoxic serum can be used for passive immunization of contacts or for the treatment of toxic cases. Many favourable results of treatment with antitoxin have now been reported, and evidence encouraging the belief that this serum is highly efficient therapeutically continues to accumulate from American³ and English sources.

PUBLIC HEALTH IN PALESTINE.

STEADY efforts in preventive medicine during the last few years in Palestine are now bearing fruit, and in the annual report for 1924 of the Department of Health special attention is drawn to the progress made in controlling malaria and trachoma, and to the valuable support that is being given by the inhabitants. Municipalities are co-operating with growing readiness in the financial upkeep and administration of the local hospitals, improvements are being made in housing conditions, and the various trades are now conducted on more hygienic lines than hitherto. The inhabitants both of towns and of villages are also giving

active assistance in antimalarial drainage schemes and in developing and improving the water supplies. Main drainage schemes, however, appear to be much less popular, though house drainage has improved. The municipalities, for the most part, have shown little appreciation of the need for improving existing conditions. This defect in the Oriental mind was illustrated in the note on public health in China in our issue of January 9th (p. 62), and appears to be very resistant to treatment. Measles was the most serious of the infectious diseases, and caused a rise in the death rate. Typhoid fever, typhus, and dysentery were limited to the Jewish population, which seems to be specially prone to infection. Tuberculosis is a grave problem, particularly in Nablus, and the incidence is high among the Jews and the Bedouin prisoners. There was less malaria in Palestine than in any previous year, the percentage incidence among dispensary patients being 3.87 in 1924, as compared with 4.9 in 1923 and 7.2 in 1922. We indicated in some detail on April 25th, 1925 (p. 795), the lines on which the malarial control in Palestine was being conducted, with special reference to the Haifa Malaria Research Unit. During the last six years co-operation has been close between the Government Department of Health, the Antimalarial Advisory Commission, the Malaria Research Unit, and the Malaria Survey Section lent by the Rockefeller Foundation. Besides drainage schemes and survey work, control of mosquito breeding in cisterns and wells and elsewhere has now been established in all municipal areas, together with notification, followed by treatment of cases of malaria. The importance of continued activity was illustrated by an alarming spread of infection in Haifa in 1923, when the antimalarial measures were temporarily relaxed. Acute conjunctivitis increased in 1924, and twelve Government ophthalmic clinics are being organized, of which four—at Nablus, Ramleh, Gaza, and Beersheba—are already in existence. All these clinics will be supervised by the varden of the British Ophthalmic Hospital of the Order of St. John of Jerusalem; they are situated in neighbourhoods where other facilities for eye treatment are absent or inadequate. More than 60 per cent. of Palestine school children show evidence of trachoma, and the chief preventive work in this disease is mainly carried on in the schools, where 50,000 children are under medical observation. In the town schools the daily treatment of infected children by the school nurse or medical orderly is found to bring about cure in some 30 per cent. of the cases. In the village schools, where the treatment has to be left to the teachers, the results have been less good. In a note on the public health work in Palestine during 1922 we referred (1923, vol. ii, p. 1270) to the existence then of eleven Government hospitals; the number was reduced to seven in 1924, and at the beginning of 1925 there were only four hospitals, with 155 beds, a further reduction being in progress. Many hospitals originally taken over by the Government were municipal hospitals before the war, and these are now being returned to municipal control subject to a certain degree of Government supervision and the maintenance of efficient treatment. During the year under review local hospital committees were formed at Gaza, Nablus, Jaffa, and Beersheba to provide and administer such services as maintenance, feeding, and laundry work. The system has so far worked well and arrangements have been made to extend it to Acre. Voluntary hospitals are doing almost the whole of the general hospital work for the civil communities of Palestine, and have been of great service to the Government in providing treatment for sick officials. In 1924 they admitted more than 23,000 patients, while the Government and municipal hospitals dealt only with 1,012 ordinary paying patients and 4,500 Government employees, infectious cases, and paupers. The Government controls the construction of all new hospitals to ensure that modern

⁴ Birmingham, for the

standards are attained. In 1922, as we mentioned, difficulty was caused by medical practitioners preferring to reside in the towns, thus leaving country districts very scantily supplied; this difficulty remains acute, though the number of licences to practise has increased rapidly. In 1920 the total number licensed was 133, in 1922 it was 306, and in 1924, 481. More Arab doctors will enter Palestine when the Arab University of Damascus improves its standards of training and examination and receives recognition. At present most students obtain their training in the excellent medical schools of the American and French Universities in Beirut. The benefit of the new medical school of the Hebrew University in Jerusalem, mentioned in our issue of March 7th, 1925 (p. 471), will soon be felt by Jewish colonists, the medical service for whom is at present inadequate. There is a great demand for midwifery training, and the Princess Mary Maternity Section of the Government hospital in Jerusalem has a long waiting list of students. Other training centres are provided by the Hadassah Medical Organization, which also administers a large number of infant welfare centres. The New Zealand Plunket Society has one infant welfare centre in Tel Aviv and one in Haifa, and the number of these centres under other voluntary organizations is rapidly increasing. Although most schools in Palestine fall far short of modern standards, yet the departments of health, education, and public works are co-operating actively in improving them. Since 1920 the number of school children inspected by Government medical officers has increased from 10,000 to nearly 20,000, notwithstanding a considerable reduction in the number of these officers.

SHORT-SIGHTED CHILDREN.

SOME little while ago the Council of British Ophthalmologists appointed a committee of eleven members to investigate the methods employed in various parts of the British Isles for the education of children suffering from defective vision due to myopia and other causes (excluding the blind). That committee has now completed its task, and its report,¹ commendably brief and to the point, has been adopted by the council. The committee's findings and recommendations are thus issued in the form of a pronouncement by the Council of British Ophthalmologists. The children under consideration are not those who are or may be expected to be technically blind—that is, those “unable to do work for which sight is essential”; these should be educated in schools for the blind; but they are those who suffer from progressive myopia, defective vision due to such causes as corneal opacities, and congenital anomalies. Special classes for these children exist. The Board of Education calls them “schools for the partially blind,” a term that the council thinks very undesirable, since it gives offence to parents and may leave a stigma detrimental to the child in after-life. The council prefers the term “myope class,” the name used by Mr. Bishop Harman, who initiated these classes in London in 1908. It concludes that the best interests of the children are served if such classes are held in association with elementary schools, for by this system contact is fostered between the defective-sighted and normal children. Individual teaching is necessary, so the classes must be small. Myope classes have been charged with “limiting the high scholastic attainment” of some children. The report faces this question, and frankly agrees that the charge is true, but it adds, “it has been found undesirable to encourage these children to follow a higher education, with the prospect of a sedentary occupation, thus incurring grave risks of serious breakdown later in life.” An investigation was made

into the provision for these children. There are now in London forty-one myope classes, providing for 915 children. In the provinces generally “with a few notable exceptions the provision for the education of the affected children is seriously inadequate.” In conclusion, the council strongly endorses the recommendation of the Departmental Committee on the Causes and Prevention of Blindness, “that further provision should be made by the education authorities for the education in myope classes or by similar methods for children with serious defects of vision requiring such facilities, and that steps should be taken to discover these cases at such an early age as will allow of preventive measures being adopted.” It adds the following recommendations of its own: (1) Children with defective sight should be examined periodically by an ophthalmic surgeon, who should prescribe the necessary treatment and educational regime. (2) In all large centres of population special classes should be established for children with such defective sight as renders them unsuitable for ordinary school education. These classes should be associated with the ordinary elementary schools, and limited to a nominal roll of twenty children in each. (3) In country districts where there are not sufficient children to form a “myope class,” instruction should be given to teachers and parents on the education and management of children with defective sight. Parents and local care committees should receive advice as to the choice of occupation for the children on leaving school. References are given to pamphlets issued by the London County Council and to papers by Mr. Bishop Harman.

THE ROGERS PRIZE.

At a time when the present Poor Law system is threatened with extinction, memories of past conflicts are revived by the announcement recently by the Society of Apothecaries of London that a prize of £150 is to be awarded for an essay on the treatment of the sick poor, in accordance with the terms of the bequest of Dr. Joseph Rogers, who died in 1889 after a strenuous life devoted to the abolition of the abuses which had hitherto disgraced Poor Law administration. Dr. Rogers, who was born in 1820, is chiefly renowned for the part he played in transforming the whole system of medical relief by founding in 1868 the Poor Law Medical Officers' Association, which united the Metropolitan Poor Law Medical Officers' Association with the Poor Law Medical Reform Association, created some twelve years before by Mr. Richard Griffin, a surgeon of Weymouth, who, with the active co-operation of the Earl of Shaftesbury, had initiated the medical reform of the Poor Law. Dr. Rogers, after playing a prominent part in securing urgently needed improvements in the sanitation of cemeteries and in abolishing the window tax, began his campaign for Poor Law reform in London in 1856, when he was appointed surgeon to the Strand Workhouse Infirmary at a salary of £50 a year; this pittance included the supply of all medicines. The institution, though licensed for 400 inmates, contained usually about 600; there was no skilled nursing, and the sick, the aged, children, and women in labour were crowded together. In 1861 Dr. Rogers persuaded a committee of the House of Commons to authorize the provision of drugs by the guardians, and, after taking an active part in the exposure of a gross case of mismanagement at another London infirmary, he accepted the invitation of Mr. Ernest Hart to make an extended inquiry into the condition of metropolitan infirmaries. From that time in his reform work Dr. Rogers co-operated closely with Mr. Hart, and prepared numerous editorial articles for the *BRITISH MEDICAL JOURNAL*, of which Mr. Hart had become editor. At many annual meetings of Poor Law medical officers, held under the auspices of the British Medical Association, Dr. Rogers recounted the steady

¹ Council of British Ophthalmologists. Report on the methods adopted in various parts of the British Isles for the education of children suffering from defective vision due to myopia and other causes (excluding the blind). London: Pullman, Thayer Street. Price 6d.

improvement that was being achieved, and his incessant efforts and untiring fight against ignorance and prejudice won for him deservedly the title of the "Hercules of work-house reform" given to him in his obituary notice in our columns (*JOURNAL*, 1889, vol. i, p. 864). At his death he left the sum of £500 in trust to accumulate until a prize of £150 could be provided for an essay on "The treatment of the sick poor in this country, and the preservation of the health of the poor in this country, or either of such subjects." The trustees are the President of the Royal College of Physicians of London and the Master of the Society of Apothecaries, who are empowered to withhold the award if no essay merits a prize. Essays must be typewritten and not previously published; they must reach Mr. Bingham Watson, clerk to the trustees, Apothecaries' Hall, Blackfriars, by May 1st, and be signed with a motto or pseudonym.

THE TUBERCULOUS DIATHESIS.

THE International Union against Tuberculosis held its fourth conference at Lausanne in August, 1924, and the Swiss National Association has recently issued a full report¹ of the opening papers and subsequent discussions on the various aspects of the tuberculosis problem chosen for the attention of this meeting. Professor Calmette opened the pathological discussion on the question of whether there exist saprophytic varieties of Koch's organism which can become virulent tubercle bacilli. The clinical question was the much debated relationship between pregnancy and tuberculosis, opened by Professor Forssner; while Sir Robert Philip, as the opener in the sociological discussion, described the effects of the antituberculosis campaign on the diminution of mortality from tuberculosis. Professor Sahli gave the first of the two public lectures on the resistance of the body to the tubercle bacillus. The most interesting paper in this published volume is, however, the second of the public lectures—that by Professor Léon Bernard on the prophylaxis of tuberculosis in the child. Its importance is no less obvious than its interest, for it represents the summing-up of the evidence accumulating of recent years in France that the tuberculous diathesis, so firmly established as a tradition in English textbooks, does not exist. The whole problem of tuberculosis is admittedly in large part bound up with the disease as it exists in childhood, and if it can be established that the child becomes infected simply as a result of contagion without the complications introduced by any consideration of inherited susceptibility, then the prevention of tuberculosis comes into line with the prevention of any other infectious disease, which it is far from doing at the present day in the minds of the public. Professor Bernard attacks the diathesis theory from several points of view. In the first place, he shows that the average weight of babies born of tuberculous mothers, excepting those in the last stages of advanced disease, is no lower than the general average. Further, the development of such infants, protected from infection, follows a perfectly normal course, and in one investigation 62 per cent. of infants born of tuberculous mothers followed a normal weight curve—a percentage comparing very favourably with any group of infants born of healthy parents. Malformations and congenital stigmata are no commoner among the offspring of tuberculous parents, and provided they are kept away from the chances of massive infection these children, supposed to be predisposed, are no more apt to contract tuberculosis than any other children. The chances of massive infection are most obvious for young babies in the family, and Debré found that out of 124 small children suffering from tuberculosis 95 had caught the disease from an infected mother, 20 from

the father, 3 from more distant relatives, and 6 from non-related persons. The chances of inhaling the tubercle bacillus in modern civilized society are always represented as high; but laboratory experiments as well as clinical observations went to show that while some sort of immunity may be developed as the result of irregularly repeated small doses of bacilli it required either a single massive dose, somewhat rare as a cause, or repeated regular moderate doses, to produce the disease; it is the repeated dose in the family circle which is responsible for most tuberculous infection. Further arguments against the diathesis theory were those bound up with certain prophylactic measures. Under the scheme introduced in France in 1903 by Grancher, healthy children from the age of 3 to 13 can be removed from tuberculous parents and boarded out under supervision in certain country districts. Of the 2,500 children already dealt with in this manner there have been only 7 cases of tuberculosis—2 fatal and 5 cured. Such figures, Professor Bernard went on to say, were remarkable when compared with the chances of tuberculous infection and death from the disease among children left in prolonged contact with infected parents; they were calculated to be 60 and 40 per cent. respectively. As the contagion may be contracted in the first few months of life, this preventive work has been extended within recent years, and as a result of close co-operation between ante-natal clinics and tuberculosis dispensaries babies can be taken away at birth from their mothers if the latter are actively tuberculous. Among nearly 300 infants thus saved from an almost certain infection there were only nine deaths from all causes. In face of these results it is not surprising that Professor Bernard refers to the word "predisposition" as being devoid of meaning when used in connexion with these children. It is true that they are under medical supervision, but the possibility of their inhaling the bacillus from chance sources is no smaller than that of any other section of the population. Despite the diathesis they are supposed to possess they contract tuberculosis with even less frequency than the general population. It is somewhat unfortunate, in view of the importance of Professor Bernard's paper, that it is not presented in English as well as French in this volume, where the opening papers in the three discussions mentioned above have been thus treated.

CONTAMINATION OF APPLES BY ARSENIC.

At a meeting of the Society of Public Analysts on February 3rd Dr. H. E. Cox, M.Sc., read a paper on the presence of arsenic in apples. Attention was drawn to the matter by the occurrence of two cases of illness attributed to the spraying of apples with lead arsenate. He stated that only five out of thirty-nine samples of Jonathan, King David, and Newtown apples were found to be free from arsenic, and eleven contained more than the statutory limit. The contamination is mainly, but not entirely, confined to the skin, arsenic having been found in the flesh of the fruit to the extent of about 3 per cent. of that on the peel. It appears that rain does not remove all the arsenic. Washing under the tap, and even scrubbing, was found to leave appreciable amounts of arsenic on the fruit, presumably owing to combination of the arsenic with the proteins of the skin. We referred on December 5th, 1925 (p. 1077), to the possibility of illness resulting from such contamination, and on December 26th (p. 1238) to a circular issued by the Ministry of Health urging local authorities to examine samples of apples likely to be so affected, and to withdraw from sale any consignments that appear to be injurious. The new and important point emerges now that the arsenic penetrates the skin, and that thus a certain amount is retained by the fruit even after active scrubbing.

SCOTTISH HOSPITAL SERVICES.

We publish in the SUPPLEMENT (at page 54) a full account of the report issued this week by the Hospital Services (Scotland) Committee. This Committee was appointed by the Scottish Board of Health to inquire into the inadequacy of the present hospital and ancillary services in Scotland, and to make recommendations for the development and maintenance of those services to meet the needs of the community. In the course of its inquiry the committee made a survey of all the hospitals—voluntary, local authority, and Poor Law—except those dealing with mental conditions, which have been inquired into by another committee. Among the principal subjects dealt with in the present report are the growth of hospitals in Scotland during the past seventy-five years; the existing shortage of beds in various types of hospital, and the number of additional beds needed to meet present requirements; matters relating to convalescent homes, Poor Law hospitals, and local authority hospital services; the need of hospital accommodation for persons of moderate means; the present financial state of the voluntary hospitals of Scotland; and the future of hospital services generally, with particular regard to the maintenance of the voluntary system. The report is signed by the chairman (Lord Mackenzie) and all the members of the committee with the exception of Mr. Joseph Waugh. The committee found a shortage of hospital facilities which it considers can be overcome without any revolutionary change in the hospital system. It recommends a Treasury grant of £900,000 to assist voluntary hospitals to provide 3,000 additional beds, the removal of the Poor Law stigma by the transfer of hospital treatment of the poor from the parish councils to the public health authorities, the institution of paying wings in hospitals, and the appointment of a Hospitals Commission for Scotland. Mr. Waugh, in a minority report, holds that the reform aimed at should be the placing of the duty of providing and maintaining general hospitals upon the health authorities of the country, assisted by State funds. The majority report, though it applies to conditions in Scotland alone, deserves careful study by all concerned in the hospital problem at large.

The next social evening of the Royal Society of Medicine will be held at 1, Wimpole Street, W.1, on Monday, March 1st. At 8.30 p.m. the President, Sir StClair Thomson, will receive the guests, and at 9.30 Dr. Gustavo Monod (Paris and Vichy) will give a short address entitled "From Cagliostro to Coué; or, Imagination as a method of treatment." The library will be open, and various objects of interest will be exhibited.

The Royal Sanitary Institute, in celebration of its jubilee, will hold an Imperial Congress in London from July 5th to 10th, 1926, under the presidency of the Right Hon. Neville Chamberlain, Minister of Health. The Lord Mayor and Corporation of London are granting the use of the Guildhall for the opening meeting. The congress will be divided into sections for discussions and the reading of papers on health and sanitary science. The Ministry of Health, the Scottish Office, the Ministry of Home Affairs for Northern Ireland, and the Ministry of Local Government, Irish Free State, are prepared to consider applications from local authorities to sanction the reasonable expenses of delegates attending the congress.

The prize lecture arranged by the Christie Hospital, Manchester, will be given by Dr. Archibald Leitch, on mule-spinner's cancer, in the Anatomy Theatre of the University at 4.30 p.m. on Friday, February 19th.

Nova et Vetera.

GRIMBALD THE PHYSICIAN.

IN a recent contribution to these columns (BRITISH MEDICAL JOURNAL, September 26th, 1925) I gave a transcript of a charter witnessed by Grimbald, and a reference to other charters which will be found in the appendix to Sir Norman Moore's FitzPatrick Lectures. Two grants by Henry I to Bath Abbey, one of them dated 1109, were also witnessed by Grimbald, and a charter to Salop Abbey of about 1122. Through the generosity of Mr. F. M. Stenton, Professor of Modern History at University College, Reading, I am now enabled to give a transcript of a very interesting and important charter relating to the daughter, Emma, and the wife, Atselina, of Grimbald. The original is in the Public Record Office (Ancient Deeds, Series A, No. 14898). The charter runs as follows:

Stephanus Rex Angliæ Archiepiscopis Episcopis Abbatibus Comitibus Justiciariis Baronibus Vicecomitibus Ministris et omnibus fidelibus suis totius Angliæ salutem. Sciatis quia coram me et concessu meo quietum clamavit et in manum meum reddidit Emma filia Grimbaldi Medici totam terram quae fuit patris sui tam eam unde saisita erat tam eam quae de jure suo erat unde saisita non erat. Et Ego coram illa et concessu ejus dedi et concessi eam totam Waltero Martello in feododum et hereditatem sibi et heredibus suis post eum. Et ipsa ei pepigit quod eam ei ad posse suum ubique warrantabit. Et de terris illis unde ipsa saisita non est quas Walterus clamavit ipsa eum jubavit ad posse suum ad eam dirationandam ad castamentum Walteri et affidavit ipsa se et heredes suos in manu Willelmi Martelli se sine dolo tenere. Et pro hoc concessu dedit ipse Walterus ipsi Emme coram me I annulum aureum. Et Johannes Martellus cujus ipsa hoc fecit consilio affidavit se ex sua parte hoc sine dolo tenere. Et Atselina uxor ipsius Grimbaldi terram suam quam tenet in pace tenebit dum vixerit de ipso Waltero et postea terra illa reddabit in dominium ipsius Walteri. Quare volo et firmiter præcipio quod bene et in pace et libere et quiete teneat in omnibus rebus et locis cum soca et saca et toll et team et infangenetheof et omnibus libertatibus ad eam pertinentibus cum quibus Grimbaldus unquam liberius tenuit vel aliquis ante eum. Testibus. G. Comite de Metellento. et R. Comite Legrecestrie. et W. Martello. et A. de Ver. et R. de Ver. et H. Bigot. et G. de Magnavilla. et E. filio Johannis. apud Wirecestriam.

The gist of all this is that Stephen informs all and sundry that Emma has quit claimed and rendered into his hand all her father's lands, both those in seisin and those which were his by right and not in seisin; and he in her presence and with her consent gave it all to Walter Martell in fee and to his heirs after him. And she has agreed that she will warrant it to be his everywhere. I am rather at sea over the next clause about those lands whereof she is not in seisin which Walter is going to claim, but I think the meaning is that she has made these over to him also and has sworn by proxy (William Martell) that she is free from guile in the matter. (For more detail about the "affidatio in manu" see Round's *Geoffrey de Mandeville*, p. 384.) And for this concession Walter gave Emma one gold ring. And John Martell, on whose advice she has done this, vouched to the absence of any guile on his part. And Atselina, wife of Grimbald, shall hold her land while she lives in peace of the same Walter, and after her death it shall return into the demesne of the said Walter. Because I wish and firmly declare that he shall hold it in peace freely and quietly in all things and places with soc and sac and toll and team and infangenetheof and all liberties pertaining with which Grimbald formerly held it and others before him. This charter passed at Worcester and is dated by Mr. Stenton 1135-1140.

With regard to the first witness, a reference to Vol. 10 of the publications of the Pipe Roll Society helps us, for the identical man is found witnessing a charter of date 1137-1138 which is there printed, and which is a confirmation by Stephen to Roger, son of Miles of Gloucester, and to Cicely his wife, of all the lands which her father Payn FitzJohn had inherited or acquired together with her own marriage portion. Both Dr. Round and Mr. Stenton identify this G. Earl of Metellent with Gualerannus Comes de Metellenti, or Waleran, Count of Meulan. Round states that the Count of Meulan was not in England between March, 1136, and December, 1137. He returned from Normandy with Stephen in December, 1137, but was back in Normandy from May, 1138, till towards the end

of that year. Stephen was at Gloucester in May, 1138, and the house of Gloucester revolted against him in 1139.

Reverting to Emma's charter, the rest of the witnesses are easily identified. R. de Legrecestre is Rannulf Earl of Chester; W. Martell must be William Martell, who is found in constant attendance on Stephen; of the two Vers, A. is Alberic or Aubrey de Vere, who was killed in 1141, and R. must be Robert de Vere, the son of Bernard de Vere, and not the younger brother, as has often been supposed, of Aubrey. From Aubrey descended the Earls of Oxford. H. Bigot is Hugh Bigot, afterwards Earl of Norfolk; while G. de Magnavilla is Geoffrey de Mandeville, who, it should be noted, attests here as a plain baron, not as Earl of Essex, to which honour he was advanced by Stephen in 1140. The last witness is Eustace FitzJohn, brother of Payn FitzJohn; from Round's *Geoffrey de Mandeville* we learn that Eustace FitzJohn deserted Stephen's cause in 1138. It will be seen that it is possible to date this charter approximately within a very short time. Henry I died towards the end of the year 1135; the Count of Meulan was out of England from March, 1136, to December, 1137, and he returned to Normandy in May, 1138. Stephen was at Shrewsbury in 1138 when Miles of Gloucester is a witness to a charter which passed there. Miles revolted in 1139 and burnt Worcester, Stephen arriving shortly after the sack of the city. Geoffrey de Mandeville attests as a baron and not as Earl of Essex, and therefore we are limited to the first five months of 1138 as the only time when the King and the witnesses could have been at Worcester.

Grimbald must have been dead at the time.* Considering the frequency with which he attests royal charters and the rarity with which medical men as a rule are found acting in this capacity, there can be no reasonable doubt that Grimbald was a Court physician, and most likely physician to Henry I. Now, at this date, the Royal physicians were priest-physicians (so far as I know there were no M.D.s then); but here we have Grimbald a married man with a wife and daughter; it is therefore most unlikely that he can have been a priest. It is possible that he may have been a secular priest; but he can hardly have been a regular one.

Soc is the power or liberty to administer justice; sac was a liberty of the lords of manors to hold pleas in causes of trespass arising among their tenants and of imposing fines for the same; toll is the duty on imports; team, the right of compelling a person in whose hands stolen or lost property is found to vouch to warranty—that is, to name the person from whom the goods were received; infangenetheof implies the jurisdiction over a thief caught within the limit of the estate to which the right belonged.

I like to imagine that Walter Martell with his one gold ring married Emma, the daughter of Grimbald and Atselina, and so took over the possession of Grimbald's lands with all the customs, sac and soc, toll and team, etc. Let us hope that, if such were the case, he got a good bargain. There was at any rate no Board of Agriculture to interfere with him, or to order a return of the number of bees which he kept! Whether Grimbald had any other children I cannot say; one would suppose not; but it is of interest to note that a Robert Grimbald was a justice of England in the next reign, when he founded an abbey in Leicestershire. His charter of foundation does not offer any evidence to show that he was connected in any way with our physician.

I can give no details about Walter Martell; but the Pipe Rolls of Henry II's reign abound with references to other

members of the Martell family: Osbert, who witnessed a charter of Stephen to Westminster Abbey, occurring in Beds and Bucks; William in Surrey and in Lincolnshire; and Gilbert witnessing a deed of 1193.

R. R. JAMES, F.R.C.S.

SMALL-POX, ALASTRIM, AND VACCINIA.

CONFERENCE AT THE HAGUE.

A CONFERENCE made up of members of a Commission of members of the Health Committee of the League of Nations, with the addition of experts, met at the Hague from January 4th to 7th, to examine several questions in connexion with small-pox, alastrim, and vaccinia. This conference was attended by Professor Ricardo Jorge, President, Professor Madsen, Sir George Buchanan, Dr. Carrière, and Dr. Jitta, members of the Commission, with the following experts: Drs. Mervyn H. Gordon and Blaxall (England), Professor Gins (Germany), Professor Soberheim (Switzerland), Dr. Levaditi (Pasteur Institute, Paris), Drs. Terburgh and Van B. Bastiaanse (Holland), and by Drs. Norman White and Olsen, representing the Secretariat of the Health Section of the League. As a result of its deliberations, the conference formulated a series of conclusions concerning the methods which should be adopted for continuing and intensifying the research work into these subjects from a general and from an international point of view.

The subjects in question had recently been considered in their general aspects by the Health Committee and by the Permanent Committee of the Office International d'Hygiène publique at a plenary session in Paris.

As a result of this discussion the following draft scheme, prepared by the President of the Conference, Professor Ricardo Jorge, was adopted as the basis of the discussions at the conference.

1. Epidemiological Part.

(a) Collect data on alastrim or alastrim-small-pox, and generally on recent epidemic appearances of small-pox which have been characterized by extreme mildness (*variola minor*).

(b) Determine as far as possible whether these manifestations confer on the disease a character which is specific from the point of view of nosography or whether they only reveal the habitual and well known characteristics of a classic small-pox (*variola vera*).

(c) Inquire whether alastrim outbreaks originate in previous cases of ordinary small-pox and if they terminate on occasion in epidemics of normal form and severity. In other words, are the two entities interchangeable—alastrim evolving into small-pox or small-pox into alastrim? Or, on the contrary, do they keep a reciprocal independence in their spread and in their evolution?

(d) Conclude whether the habitual methods of prophylaxis against small-pox (isolation, disinfection, vaccination) should be applied with the same vigour to alastrim-small-pox.

(e) Put together the facts about epizootic diseases of the nature of variola (cow-pox, clavelée, or sheep small-pox, avian small-pox, etc.) and compare their noso-epidemiological characteristics in their relation with small-pox.

Inquire specially whether appearance of these epizootics can be connected with human small-pox. In other words, whether these zoo-variolas only spread where small-pox is prevalent, and whether they disappear or become rare in regions where small-pox has ceased to be prevalent.

2. Experimental Part.

(f) Take up the study of biological tests of variola, controlling their technique and their diagnostic value. Determine the significance of those cellular inclusions called "corpuscles de Guarnieri," "de Prowazek," etc.

(g) Submit to comparative experiment on animals the viruses of small-pox of different origins, alastrim, cow-pox, and other zoo-variolas, with the object of determining the characteristics of the lesions produced by these different infections and their immunizing action. Deduce from these researches conclusions on the specificity of these different forms.

Make a special investigation to see if alastrim and variola immunize one against the other, and how they behave from the point of view of immunity in regard to vaccinia.

Determine from observation and experimentation the duration of immunity produced by variola, alastrim, and vaccinia, in the case of direct and also of crossed infections.

(h) Deal with the question of the identity of the viruses of

* Grimbald was certainly alive in 1130, and probably in 1132 also. Stubbs, in the *Constitutional History of England*, vol. i, p. 340, mentions the fact that Henry I was inclined to remit the Danegeld: "partly under the advice of his physician Grimbald and partly under the impression made by a strange dream, he vowed, it was said, in 1132 to forego the tax for seven years." A footnote gives the story of Henry's nightmare; very vivid it reads in the Latin of John of Worcester, but it is too long to add here. Grimbald, as a landowner, would have disliked the Danegeld as much as we all dislike paying our income tax at the present day. This hated tax of two shillings on the hide occurs for the first time in A.D. 991; it was the tribute paid to the Danes to keep them quiet in the eastern shires, in which for the most part they had settled. Under the rule of the Danish King Canute the Danes became merged in the Anglo-Saxon race; yet the Danegeld remained in force and William the Conqueror trebled the rate—that is, six shillings on the hide—and it was not until 1163 that the Danegeld finally disappeared from the Pipe Rolls, and then it was succeeded by a tax, which under the name of *donum* or *auxilium* and probably levied on a new computation of hidage must have been a mere reproduction of the old tax."

variola and vaccinia, and with the production of vaccinia by the inoculation of small-pox on bovine animals.

Ascertain whether alastrim lymph can be utilized as a preventive measure against variola, replacing the Jennerian vaccine. Make similar attempts in the case of sheep-pox in order to ascertain whether "ovination" is possible.

(i) Propose a process of measuring the virulence of lymph, by means of which it will be possible to establish vaccinal standards. Determine practical rules for the control of vaccine lymph.

(j) Study the spontaneous variations in the activity of cow-pox in the course of its passage through calves and, when it is humanized, in passage from arm to arm; study the proceedings which can be adopted to increase virulence which is attenuated. Set out the effects and possible dangers of exaltation of virulence.

(k) Study the tissues of election in the case of the viruses of variolas and vaccinia, and give an opinion on the use of vaccines which are termed "purified vaccines," notably of neuro-vaccine.

(l) Make inquiries and researches on the morbid conditions which may follow vaccination in man.

(m) Examine the serological reactions of man and animals which follow variola infections, and particularly the neutralization of the viruses by serums *in vitro*. Undertake research on the serum of animals convalescent from zoe-variolas with the object of obtaining a therapeutic serum applicable to the human case.

This draft scheme is discussed in a leading article on variola research at page 293, where reference is made also to the appointment this week by the Minister of Health of a Committee on Vaccination.

Scotland.

CENTRAL MIDWIVES BOARD FOR SCOTLAND.

At the meeting of the Board held on February 4th it was intimated that the following members had been appointed for a period of five years from February 1st, 1926: Miss Alice Helen Turnbull, Miss Kate Leslie Scott, and Miss Mary Elizabeth Cairns (appointed by the Scottish Board of Health); Sir Archibald Buchan-Hepburn, Bt. (Association of County Councils of Scotland); Bailie Mrs. Ella Morrison Millar (Convention of Royal Burghs); Miss Margaret Macpherson White (Queen Victoria Jubilee Institute for Nurses, Scottish Branch); Dr. Archibald Kerr Chalmers (Society of Medical Officers of Health of Scotland); Professor B. P. Watson, M.D. (University Courts of the Universities of Edinburgh and St. Andrews); Professor John M. Munro Kerr, M.D. (University Courts of the Universities of Glasgow and Aberdeen); Dr. James Haig Ferguson (Royal College of Physicians of Edinburgh, the Royal College of Surgeons of Edinburgh, and the Royal Faculty of Physicians and Surgeons of Glasgow); Dr. R. C. Buist and Dr. James B. Miller (Scottish Committee of the British Medical Association). The meeting unanimously reappointed Dr. James Haig Ferguson as chairman, and Sir Archibald Buchan-Hepburn as deputy-chairman, for the ensuing year. The meeting appointed committees for penal, finance, and examination purposes, and approved the lists of examiners and recognized institutions, with the teachers attached thereto, for the training of midwifery nurses, and gave instructions for the citing of certain penal cases.

TESTIMONIAL TO DUNDEE RADIOLOGIST.

A meeting was held on January 26th in the City Chambers, Dundee, at which Lord Provost High presided, for the purpose of arranging for the presentation of a testimonial from the public of Dundee to Dr. George A. Pirie. Dr. William E. Foggie said that the medical profession had taken up the case of Dr. Pirie, who had done pioneer work in the department of radiology for many years, and had suffered severe physical injuries because of the absence of protective measures in the early days of work in this department. Mr. D. A. Anderson explained that the trustees of the Carnegie Fund had been approached with a view to putting the claims of Dr. Pirie before them on account of his continual self-sacrifice, which had really amounted to a whole lifetime of heroism. The Carnegie trustees had intimated that they were pre-

pared to consider the project favourably, but that they thought it wise to find out in the first place what the city of Dundee was prepared to do.

ROYAL DISPENSARY AND VACCINE INSTITUTION, EDINBURGH.

The Royal Dispensary and Vaccine Institution, West Richmond Street, Edinburgh, which was founded by Dr. Andrew Duncan in 1776, has entered upon the 150th year of its existence. Lord Provost Sir William Sleigh presided on January 30th at the annual meeting of the dispensary, and referred to the very valuable contribution which its services had made to the social needs of the city over its long period of existence. It was satisfactory to find that the opportunities for obtaining free medical services and treatment had been largely utilized by the poor of the district in which the dispensary was situated. During the past year over 2,000 cases had been treated and over 1,000 had been visited in their own homes by students attending the dispensary. A child welfare clinic which had recently been established was doing important work, and a total of 1,654 cases during the year was reported. The financial position was satisfactory. The total funds available were £8,406, with a surplus of revenue over expenditure of £64.

PROPOSED EXTENSION OF DUNFERMLINE HOSPITAL.

At the annual meeting of the Dunfermline and West Fife Hospital subscribers held on January 25th, Provost D. A. Fraser presiding, it was agreed to call a special meeting of the citizens of Dunfermline to open an appeal for funds amounting to between £30,000 and £40,000, to enable the managers of the hospital to extend the institution. It was stated that this extension had become essential for carrying out the work now required of the institution in a satisfactory manner, and it was believed that the scheme would have the full support of the citizens of the town and district.

EDINBURGH MATERNITY HOSPITAL.

The directors of the Edinburgh Royal Maternity and Simpson Memorial Hospital have received intimation from the Queen's private secretary that Her Majesty has accepted the suggestion from the board and has pleasure in becoming Patroness of that institution. Former patronesses of the hospital were Queen Victoria and Queen Alexandra.

Ireland.

MEDICAL REGISTRATION IN THE FREE STATE.

The standing orders having been suspended, the Medical Bill, 1926, which has for its object to continue in operation until August 21st next the Medical Act, 1925, has passed through all its remaining stages in the Dail and will be presented in due course to the Senate.

DANGER OF SMALL-POX.

The General Council of the Royal Academy of Medicine in Ireland has adopted the following resolution:

That in view of the outbreak of small-pox in certain parts of England, following on the decline of vaccination in that country, the President and Council of the Royal Academy of Medicine in Ireland, having had their attention drawn to the decline of vaccination in this country, deem it their duty to urge the necessity for vaccination of all young children and of immediate revaccination in the case of adults who are likely to come in contact with cases of small-pox.

Ireland has been free of small-pox for about two score years. Ten years ago a sailor was found with a very mild form of small-pox in Dublin, and was isolated at once. He had only three of the diseased spots, but in the few hours that he was in contact with the general public he had infected one other person. Since that time no case has arisen, but the history of small-pox in Ireland teaches that the country seems to be more subject to the virulent type with high mortality than to the milder form. Dr. Day, the medical superintendent of the Cork Street Fever Hospital, has stated that he does not like to think of what would happen in Dublin should the disease make

its way theré from England. He related instances in his experience of the almost unbelievable insidiousness of the infection, showing that no one was safe. In the last serious epidemic in Dublin an invalid lady living in the county got small-pox in a bad form. He succeeded in tracing its origin to almost momentary contact with a girl by a young dressmaker who was employed in the shop where the family of the lady had their clothes made. Dr. Day said that one of the greatest dangers of small-pox was the difficulty of its diagnosis, and the younger generation of medical men had, for the most part, never seen a case of the disease. Every hour that the person who had contracted it remained open to contact with others sent the disease further through the general community. As far as he had learned, the present epidemic in England was of a mild type, but it was a fact that, without any apparent reason, the virulent and deadly form often appeared in the middle of an epidemic of the less dangerous type. No parent, he said, would neglect the vaccination of his children if he once saw the shocking sufferings of a child with small-pox, and visualized the effects of the disease, even should life be saved. Before vaccination was made compulsory the country was full of people who lost their eyesight as the result of small-pox in childhood. With so many unvaccinated children there was nothing to prevent that horrible state of affairs from arising again should the disease find its way into any of the ports. He regarded the neglect of vaccination of children as arising from sheer carelessness. Should a case appear in Dublin there would, he added, be a stampede to the doctors to secure the protection of vaccination, the only preventive. Another Dublin practitioner expressed surprise that the Government authorities were not insisting on the observance of the law of vaccination. He pointed out that by stringent regulations the Minister for Agriculture had kept out foot-and-mouth disease, which ravaged the cattle population of England; but the more serious threat to the health and lives of the people would appear to excite little official activity. While there is no occasion for a scare, the opinion of medical men is that nothing should be left undone to prevent the spread of the disease in Ireland.

India.

INDIAN SANITARY REPORT.

THE annual report of the Public Health Commissioner with the Government of India for 1923, which has been recently published, is divided into eight chapters, dealing with the European army, the native army, the general population, jails, vaccination, medical institutions, sanitary works, and medical research. The death rate of the European army in 1923 was 3.75 per 1,000, the lowest on record with the one exception of 3.26 in 1913; the sick rate was actually the lowest, the disease with the greatest reduction being influenza. In the native army the death rate (5.88) and the sick rate (20.63) both show a great improvement over the rates of the past ten years; the former is somewhat higher, the latter fractionally lower, than the rates of the quinquennium 1910-14, which were 4.39 and 20.7 respectively. The report states: "It is difficult to resist the conclusion that this marked improvement in the health statistics of the Indian army is due to the introduction of the station hospital system in 1918, and to its growing efficiency." While all, or almost all, who have served in Indian regiments under the old system, when the medical officer was a regimental officer, will feel a sentimental regret for the passing of the system they knew, with its traditions of over a century, it is satisfactory to hear that the change has been justified by results. In the general population the death rate was 25.00, against 24.02 in 1922 and a quinquennial mean of 36.85; the birth rate was 35.06, as compared to 31.85 in the former year. It is probable that registration in India is now fairly accurate as regards the actual number of deaths, though it will be long before the same can be said of the different causes of death. Plague is more accurately recorded than any other cause of death, and in 1923 was more widely spread than

in the previous year, causing 229,149 deaths, as compared to 77,615 in 1922. Even so, the figures are small compared to those of some previous years. Plague has now been epidemic in India for thirty years—since 1896, just a generation—and seems likely to persist permanently as an endemic disease. The only provinces which did not show an increase in 1923 are Bengal, Assam, and Burma. The jail population in 1923 was slightly lower than in 1922. Both death and sick rates were lower than in the previous year. The vital statistics of jails are the only ones concerning the civil population which are absolutely trustworthy. Vaccinations increased from 9,345,106 to 9,834,460; all provinces showing a rise except the small North-West Frontier and Ajmir-Merwara provinces. Medical institutions, hospitals, and dispensaries of all classes increased in number from 3,535 to 3,634, and their patients from 36,875,222 to 38,059,386; surgical operations rose from 1,150,628 to 1,194,664. These figures give some idea of the scale of medical work in India. There are now seven research laboratories: two in the Punjab, the Central Research Institute and the Pasteur Institute, both at Kasauli; two in Madras; and one each in Bombay, Assam, and Burma.

PUBLIC HEALTH IN BURMA.

Active steps are being taken to lower the high infantile mortality rate in Burma, the chief causes of which are stated in the annual report for 1924 of the Public Health Administration as being unskilled midwifery, improper feeding of infants, and insanitary housing. The Burma branch of the Indian Red Cross Society is giving financial assistance to the numerous infant welfare societies which have been formed, and several of these societies are in receipt of Government grants. Baby weeks similar to those in England were inaugurated originally by Lady Reading, and have been held with great success in many Burmese towns. In the year under review the province was visited by an exceptionally virulent epidemic of cholera, the deaths from which were 8,083, as against 1,488 in 1923. In some cases this outbreak was shown to be water-borne as a result of careless disposal of excreta and soiled linen, and in others it was food-borne. A widespread infection in the Kyaukse district was quickly controlled by the prompt disinfection of the wells with permanganate solution, isolating the sick, and cremating corpses and their effects soon after death; the early notification of cholera cases by the village headmen was a prominent factor in the rapid success of the campaign and the limitation of the spread of disease. Preventive inoculation with anticholera vaccine has been extensively practised, and of the 38,368 persons thus treated only 131 were reported to have contracted the disease; of these 87 were in one district, and there was clear evidence that delay in treatment or the existence of massive infection was the cause of failure. The number of deaths registered as due to plague in 1924 totalled 5,491, as against 7,606 in 1923. In this disease prophylactic inoculation is finding favour, especially in the towns, and it is undoubtedly the cause of the lessened mortality. The report describes the special endeavour now being made to solve the problem of beri-beri, though so far there has been little success. The details of the 95 fatal cases reported in 1924 suggests that Indians are not only more susceptible, but succumb more easily to the disease than do the Burmese. Investigation of an outbreak of epidemic dropsy showed that rice was the staple food of the sufferers, and had been obtained from supplies which had deteriorated from long storage and infestation by weevils. Goitre appears to be particularly prevalent in those hill areas of Burma where maize and millet are the staple foods. In some of these districts successful results have been obtained by the administration of iodine to school children. An antimalarial survey of Akyab town revealed that of 2,756 children under 10 years of age 483 had enlarged spleens, extending down to the umbilicus in the majority of cases, and this enlargement was most marked in children aged 4 to 6. The survey also indicated that malaria was less prevalent in the central parts of the town as compared with the outlying districts where breeding grounds were present, including pools in the upper reaches of the smaller creeks, tanks, excavations, and paddy-fields. Inspection of

15,874 school children showed that only 492 were unprotected against small-pox. There was, however, a considerable increase recorded in the percentage of children with defective eyes, enlarged tonsils, and adenoids, due to the more stringent examinations now being made. Increased attention is now given in Burma to general hygiene. A hygiene publicity officer has been appointed to provide instruction on general sanitation, maternity, and child welfare by means of leaflets and lectures. We referred on February 21st, 1925 (p. 383), to the laying of the foundation stone of the Hygiene Institute in Rangoon by the Governor of Burma. The building and equipping operations have made good progress under the direction of Major Jolly, C.I.E., and Dr. G. Mackey, late assistant director of the Central Research Institute at Kasauli.

BLIND RELIEF ASSOCIATION OF BOMBAY.

In 1920 Mr. C. G. Henderson, I.C.S., when resident in Bombay started an association for work amongst the natives for the relief and prevention of blindness. Eye affections are particularly prevalent in India, since the heat, the atmosphere, and the brilliant sunlight throw a great strain upon the eyes. The crowded villages and sometimes the lack of effective sanitation accounts for the spread of contagious eye diseases, and cataract and trachoma take a heavy toll of sight. Since its inception the work of the Blind Relief Association of Bombay has increased greatly. Mr. Henderson has ceased to be its president as he has returned to England, and he has been succeeded by Mr. R. G. Gordon, I.C.S., the present collector of the district. There is an eye surgeon, whose services have been lent and paid for by the Government; he has charge of the eye work in the civil hospital, and trains field workers, who travel regularly through the villages in the surrounding area. He himself visits these villages, selecting the patients who need to go into hospital for surgical treatment. In 1920 the operations performed numbered 465; in 1924 they reached 1,248. The cases treated in the civil hospital and the dispensaries (movable tents) have increased from 7,821 to 14,248 in the same period. The association received a sum of 11,590 rupees during 1924, mainly from native subscribers. The money is used largely in the extension of the field work, which is obviously of the greatest value in the prevention and treatment of eye diseases.

Correspondence.

THE STATISTICAL STUDY OF CANCER.

SIR,—In a lecture, printed in your issue of January 30th (p. 175), Dr. Cramer refers, briefly and inaccurately, to a statistical investigation for which Dr. Methorst, Professor Niccforo, and I are mainly responsible. It is not, I admit, very easy to make sense of Dr. Cramer's remarks. He actually says that the conclusion, derived from experimental study, that if a primary cancer has been induced in one organ a primary cancer cannot develop in another organ, "would also explain another very curious fact which seems to have been overlooked by statisticians." Grammar would seem to require the other "very curious fact" to be statistical data of the subsequent pathological histories of persons known to have been affected by cancer of one primary site, given in far greater detail than any existing system of death certification supplies. But what Dr. Cramer appears to mean is that (a) the League of Nations Subcommittee only investigated the statistics of England and Wales and Holland and (b) was not aware that the gross mortality rates from cancer were approximately the same in the two countries. Addiction to statistical methods may, of course, imply some lack of intelligence in the addict, but we are not quite so dull as Dr. Cramer supposes. One of the reasons for including Italy in our study was that, of the countries with well organized statistics, Italy enjoys the lowest gross mortality from cancer although her rate for uterine cancer is higher than that of Holland.

I should not, however, have troubled you with this letter merely for the sake of pointing out a misstatement. But,

as you remarked in your editorial of January 23rd, the statisticians' report is so concise that some suggestive results may easily be overlooked.

Although not, perhaps, strictly deducible from the experimental results of Dr. Murray, the suggestion does arise from them whether the circumstances which favour the development of cancer of one site do, other things equal, tend to hinder the development of cancer of another site. In the report of the statisticians the point was not discussed, because for various reasons data could not be provided by all three countries, but in Tables Va and Vb the results of an analysis of English data are provided. The material consisted of the rates of mortality from (1) cancer of the breast, (2) cancer of the uterus, (3) all other forms of cancer, (4) all causes of death other than cancer, for married women and widows, aged 45 to 64 years, in each of seventy-four English county boroughs. The experience covered the decennium 1911-20. The final result was that there was no sensible correlation (0.0751 ± 0.078) between the rates of mortality from cancer of the breast and cancer of the uterus in married women when the rates of mortality from other forms of cancer and from causes other than cancer, as well as the percentages of married women, were made constant by the method of partial correlation. In other words, when we had stabilized as well as we could the general (non-cancerous) mortality—which is some measure of general environment—the mortality from all other forms of cancer, and the civil state (to reduce the known influence of fertility), the two rates of mortality behaved as independent variables. It may be remarked, too, that while the rate of mortality from cancer of all forms other than cancer of the uterus and breast (keeping rates for cancer of the breast and cancer of the uterus and percentage married constant) was highly correlated with the rate of mortality from non-cancerous causes (0.4275 ± 0.071), the rate for cancer of the uterus was not correlated significantly (0.0985 ± 0.078), and that for cancer of the breast was negatively correlated (-0.2917 ± 0.075), with the rate of non-cancerous mortality.

So far as these results go, they suggest that at least the rates of mortality from cancer of the breast and uterus vary independently one of another. It is necessary to make so elaborate an analysis because the mere fact that the gross correlations of cancer of both sites with cancer of all other sites are large and positive might be a mere expression of the fact that when diagnosis is good at one site it is good at other sites.

At present, then, we have no statistical evidence that the causes which favour the development of one form of cancer hinder the development of another form, and Dr. Cramer's dictum that "The more frequent development of cancer in the intestinal tract among Dutch women protects them against the development of cancer in the breast" is just as helpful as the statement that the reason why so few people die of encephalitis lethargica is because so many people die of cancer.—I am, etc.,

Loughton, Feb. 3rd.

MAJOR GREENWOOD.

THE ACTION OF PITUITARY EXTRACT ADMINISTERED BY THE ALIMENTARY CANAL.

SIR,—Dr. Knaus (February 6th, p. 235) writes: "Clinical observations of this kind are by the nature of things extremely difficult to interpret, as they lack the necessary controls." All clinicians will agree with this statement, and therefore a very large number of observations must be recorded before any conclusion can be drawn.

Diabetes insipidus is a sufficiently rare disease to make it unlikely that the experience of one individual will suffice, and therefore many single observations may assist. Although more than half a dozen cases of diabetes insipidus have come under my care since it was known that pituitary extract controlled the diuresis, all except one were treated by injections, since I assumed that the administration of pituitary extract by the mouth would prove useless.

Quite recently I have had under my care in hospital a typical case of the disease in a woman who experienced great discomfort after hypodermic injections of pituitary extract. I decided to try administration by the mouth,

which proved quite useless; even when the dried gland corresponding to 2 grams of the fresh gland were administered daily in the form of pills triply coated with salol. Unfortunately I have no proof of the potency of the dried gland, but only that it was from a reputable firm.

O. LEXTON.

DYSENTERY IN MESOPOTAMIA.

SIR,—On January 30th (p. 202), in commenting upon the recently issued Report on the Health of the Army for the year 1923, the subject of the relative incidence of the amoebic and bacillary types of dysentery in different localities is mentioned. You refer to the report as showing that nearly all the cases (of dysentery) occurring in Iraq were amoebic, whereas in Egypt only 35 out of 64 cases were of that type; and you remark that this bears out much of what has been previously recorded in connexion with the geographical distribution of amoebic and bacillary dysentery.

I am unable to agree with the latter statement, my experience during nearly five years of bacteriological work in Iraq during the war being entirely the reverse. In 1916, at the request of the Medical Advisory Committee then in Iraq, Mr. C. L. Boulenger and I undertook an investigation on the etiology of Mesopotamian dysentery in order to settle this point. I have not the exact figures by me, but the report on this work subsequently issued showed that, of roughly 250 consecutive acute cases, 51 per cent. were proved bacillary by isolation of the bacillus from the stools, whereas 26 per cent. only were amoebic. The report ventured the opinion that, had it been possible to get all these cases sufficiently early, the former group would have been even larger, many of the undiagnosed 23 per cent. undoubtedly belonging to it. The unavoidable delay which sometimes occurred before examination of the stools would tend to favour a relatively high amoebic figure, whereas the bacillary agent is not so readily demonstrated as the severity of the inflammatory process wanes.

Colonels Wenyon and Ledingham, members of this committee, found that these figures agreed with what they were led to expect from their own observations and from their experiences in the Eastern Mediterranean. In a report on Iraq, issued before the above investigation was completed, these two observers stated:

"... already it would appear that the bacillary form is probably the more frequent, as indeed has recently been found to be the case in the Eastern Mediterranean and Egypt, where extensive series of cases have been thoroughly worked out."

Subsequent to the issue of our report during the next three years I examined many thousands of stools from dysentery patients in the same area, and in all of these the amoebic percentage was fairly constant at the figure stated. At one time, indeed, it rose alarmingly, but that was due to the idiosyncrasy of an officer working in my laboratory who never could master the differences between *E. histolytica* and the non-pathogenic amoebae. To him even the macrophage was a frequent stumbling-block. If the Report on the Health of the Army for the year 1923 is correctly quoted by you a great change must have come over the etiology of Mesopotamian dysentery.—I am, etc.,

KNOWLES BONEY, M.D., M.R.C.P.,

Major R.A.M.C. (ret.).

Llandudno, Jan. 31st.

** The figures on which the statement as to the number of cases of amoebic dysentery in Iraq, Turkey, and Egypt respectively is founded will be found in page 7 of the report. They are as follows:

	Total.	Amoebic.	Bacillary.
Iraq ...	207	181	?
Turkey ...	112	1	61
Egypt ...	64	35	29

"ARCHIVES OF DISEASE IN CHILDHOOD."

SIR,—The article in your issue of January 30th (p. 209) announcing the appearance of the *Archives of Disease in Childhood* was very welcome, both because British pediatrics is to be represented by a journal of its own and because of the enterprise of its producers and the British Medical Association in co-operating in the work of its publication.

Would that those responsible for selecting a title had also had the enterprise to break away from an out-of-date definition of their subject. "Archives" denotes the place where the records of the past are stored, and is, therefore, a suitable receptacle for the term "Disease of Childhood."

The title required is one which does not suggest that "disease" is the sun round which their system of study revolves. Surely nowadays the centre-point and primary objective is the study of normal development and the detection of the earliest evidence of its disturbance, with a view to the maintenance of the physiological, whereas that of "Disease in Childhood" represents rather the failure to attain that objective. True, the study of the causes of disease and their elimination is the chief part of the primary objective, but the title should be based on what the subject is out to succeed in doing, and not on what it fails to do.

It is quite clear that there is an influential body of opinion which dislikes "pediatrics," probably because of its being "made in U.S.A.," but it is equally clear that it is too late to refuse a term that has been accorded general acceptance elsewhere and is slowly making its way here, in spite of our prejudice against any new thing, and for the very reason that it does not suggest the diagnosis and treatment of disease as the chief reason for the existence of this branch of medicine.

Doubtless English terms have their attraction, and I notice that in your *Epitome of Current Medical Literature* the only really English title is that of "Diseases of Children." Why is it in these days of infant welfare clinics and the examination and observation of well children with the idea of keeping them "well" that the archaic term "diseases of children" is retained?—I am, etc.,

London, W.1, Feb. 3rd.

JOHN S. FAIRBAIN.

** Meanwhile disease in childhood may be expected to continue to prevail. The promoters of the new periodical deliberately decided to make it clinical, though not excluding, of course, the discussion of the detection of the earliest evidence of disturbance of health. No doubt when preventive medicine has extinguished disease in childhood the *Archives* also will become extinct.

OPERATIVE TREATMENT OF PERFORATED GASTRIC AND DUODENAL ULCER.

SIR,—Mr. Arthur J. Evans (BRITISH MEDICAL JOURNAL, January 30th, p. 184), in an article on operative treatment of acute perforated ulcer of the stomach and duodenum, states that perforation is often "seasonal." As the following figures show, this is not borne out in a

series of 387 cases of this condition admitted to the Glasgow Royal Infirmary during the years 1913-24:

January	...	39	July	...	38
February	...	31	August	...	36
March	...	31	September	...	24
April	...	38	October	...	31
May	...	28	November	...	28
June	...	30	December	...	33

Mr. Evans publishes a series of 64 cases, and from this makes certain deductions—for example, that gastro-enterostomy should be performed at the same time as closure of the perforation. Of course, he makes certain reservations—for instance, that gastro-enterostomy should only be done by surgeons who are used to gastric surgery. In my series gastro-enterostomy was performed by such surgeons, yet the death rate is very much higher than where gastro-enterostomy has not been done. Instead of gastro-enterostomy I have been performing a modified pyloroplasty, the details of which will appear in a paper on these cases. This operation occupies only a very few minutes, and I cannot see where gastro-enterostomy has an immediate advantage over it. In Mr. Evans's last paragraph he states that gastro-enterostomy is to be done "if the patient's condition will allow it"—that is to say, the more desperate cases are to be denied this beneficial operation. If it is such a boon in the less severe, why not do it in the more severe? Because it is too great a tax on the patient's strength? But Mr. Evans assures us that the combined operation "does not entail any increased risk." Does gastro-enterostomy prevent the risk of another perforation? No. In one of my series where gastro-enterostomy had been performed perforation took place at the pylorus, whilst another had a perforation distal to the anastomosis.

On the question of drainage Mr. Evans and I are at one. My usual method is to drain the pelvis by means of a Keith's tube for a few days. If much gastric or duodenal contents have escaped, I put another tube into the right kidney pouch. None of my cases has developed a residual or subphrenic abscess. In this I have been extremely fortunate.

Mr. Evans gives the mortality rate of his last 12 cases in which the combined operation was performed. It is 8 per cent. If I take my last 10 cases where simple suture was performed the mortality rate is *nil*. (One of these had been perforated seventy-two hours and another twenty-two hours before operation.) But if I take all my cases the mortality rate is 20 per cent.; so that I think it is rather fallacious to argue from a small number of cases and state that the mortality rate is so-and-so. The correct mortality rate can only be found by examining a large number of cases, and it will be found to be much larger than one would wish.

Mr. Evans cannot compare his results obtained by simple suture with those of the combined operation, as he practically admits that the former operation was only performed (latterly, at all events) in cases deemed to be too ill to stand the combined operations. In his first seven cases, would the performing of gastro-enterostomy have saved the two who died? I think not.—I am, etc.,

Glasgow, Feb. 1st.

JOHN DUNBAR, M.B., Ch.B.

ETYMOLOGY OF "ORTHOPAEDICS."

SIR,—In your issue of January 30th, in an interesting article on manipulative surgery (p. 204), when speaking of orthopaedic surgery you say—"originally concerned mainly with deformities and diseases of bones and joints in children—whence the name, now rather out of date; but adults have benefited," etc. (The italics are mine.) I venture to submit that it is your etymology which is out of date—indeed, which is incorrect.

Surely "orthopaedic" is derived from *ὀρθός*, straight, right, true; and *παίδευω*, to educate, to train. The science of orthopaedics is to "train aright" structures which are distorted, or deformed, or defective. Of course, *παίδευω* is derived from the same root as *παῖς*, *παῖδος*, a child; but to "train aright" or to "straighten something which is amiss" is not, and never has been, confined to children;

and to my mind to limit the meaning of orthopaedic thus is—well, also childish. According to your etymology orthopaedic means "straight child," whereas I contend it means "to train straight" (what is defective). Surely this is more scientifically accurate, and can never be "out of date."—I am, etc.,

W. B. MACKAY, M.D., etc.

Berwick-upon-Tweed, Jan. 31st.

** The etymology of "orthopaedics" is a question which keeps cropping up at irregular intervals. The *New English Dictionary* gives under "orthopaedics" a reference to orthopaedy, a word which is now, we believe, obsolete in English, though current in French. It makes no reference to *παίδευω*, giving *παῖδιον*, a child, *παῖδα*, rearing of children. "Orthopaedics" it defines as "relating to or concerned with the cure of deformities in children, or of bodily deformities in general." The *Concise Oxford Dictionary* gives "orthopaedy, the curing of deformities in children or others," from *παῖδα*, the rearing of children, from *παίδευω*, train, from *παῖς*, a child. Littré's *Dictionary* (sixth edition) gives the derivation as from *παῖς*, but the definition does not distinctly limit the application of orthopaedic methods to children.

INDIVIDUAL OVERDOSE OF ULTRA-VIOLET RAYS.

SIR,—In recent literature on ultra-violet light little mention has been made of a train of symptoms, the same in all cases, which occurs in certain individuals exposed to what is otherwise a normal dose, without marked erythema.

After a general irradiation there is marked lack of that feeling of general well-being, and the usual exhilaration is replaced by a feeling of depression. Following a latent period of two to four hours after exposure, headache, a feeling of chilliness, pain in the back, conjunctival irritation, nausea with occasionally vomiting, distaste for food, and general depression ensue. Diarrhoea is an occasional concomitant. The next day brings general lassitude with vague depression, which gradually passes off. There is no evidence of dietetic errors. The condition appears to occur in one out of twenty-five patients treated. It has been met with at all ages, in women more often than men, and chiefly in dark or red haired persons. No reaction has been observed in any blonde. The normal dose cannot be reached by gradation, and the patient appears always intolerant of what is, otherwise, the usual dose. These patients cannot tolerate their own maximum dose indefinitely, and after some time additional sensitization appears to occur and the symptoms mentioned are exhibited, necessitating a further reduction of the time of exposure.

The phenomena were first observed when using carbon arc lamps with cored carbons, and were attributed to the heat generated. The same effects have since been observed with tungsten arc and mercury vapour lamps with their proportionate shorter doses.

There is a curious resemblance between these symptoms and those met with in some cases after the x-ray treatment of carcinoma by large doses. Some cases of breast cancer and secondary epitheliomatous glandular deposits have exhibited almost identical symptoms. In addition, a local area which had been exposed to x rays appears to react more readily and more markedly when exposed to ultra-violet light than a previously untreated area. It is agreed that the ultra-violet spectrum approaches the x-ray spectrum, and in diseases of the skin very similar results are obtained by both forms of therapy, the x rays appearing to be the more powerful measure.

From the observations made in this type of case, now that artificial sunlight treatment is being used in all classes of case and by all manner of persons, one wonders whether ultra-violet irradiation is so innocuous as is generally supposed and whether indiscriminate, prolonged, and sometimes unskilled administration may not be followed by untoward results as in the early history of x rays.—I am, etc.,

Royal Infirmary, Sunderland Jan. 27th. PAIGE ARNOLD, M.B.

A FORTUNATE ESCAPE FROM SYMPATHETIC OPHTHALMIA.

SIR,—With reference to Dr. Lawson L. Steele's interesting memorandum on "A fortunate escape from sympathetic ophthalmia" in the *JOURNAL* of January 30th (p. 187) one feels that this title may strike a somewhat too optimistic note. The great majority of experience goes to show that sympathetic ophthalmitis is a calamity that may ensue at any time up to twenty years or even longer after the original perforating injury was sustained. The ability of the eye to make a good recovery from the initial wound depends on the amount of trauma suffered by the ciliary body. Where the wound does not involve the ciliary region the prognosis would be hopeful, even good, if the lips of the wound are free from uveal tissue. Any wound that involves the ciliary region (except perhaps in young children) is so liable to entail a sympathetic ophthalmitis that excision of the eye is almost a necessity. This case seems to bear out the above principles, for Dr. Steele mentions a corneal wound with its perforating extremity towards the centre of the cornea, and so one implies that the ciliary region was not implicated. The recovery of the eye to a vision of 6/12 is so good as to make certain that the ciliary body escaped actual damage. Dr. Lawson Steele's concluding epigram is only too true if the ciliary body itself is wounded.—I am, etc.,

GEORFREY B. LOWE, D.O.Oxon.

St. Leonards-on-Sea, Jan. 30th.

XEROPHTHALMIA.

SIR,—Mr. J. S. Arkle's remarks on xerophthalmia, reported in the *JOURNAL* of November 21st, 1925 (p. 952), are of interest. In Trinidad this conjunctival condition is common amongst the native population, and particularly so among the East Indian community and those suffering from advanced ankylostome infection. The condition seems to start in the region of the internal canthus and gradually spreads until the whole of the bulbar conjunctiva becomes dry and crimped and appears like thin smoked parchment. Corneal ulceration ending in keratomalacia finally ends the clinical picture.

If treatment is started in the very early stage the result is promising, but in the advanced stage where the conjunctiva is darkened the result in my experience is disheartening. The condition was present in cases of advanced anaemia and emaciation resulting from ankylostomiasis. Treatment consisted in applying drops of castor oil to the conjunctiva three or four times daily, followed by anthelmintics of thymol or carbon tetrachloride; later, cod-liver oil and vitamin food, including metagen gr. v. The results on the whole were not encouraging.—I am, etc.,

H. E. KING FREYTS, F.R.C.S.Ed.

Weymouth, Feb. 7th.

FINAL NURSING EXAMINATION.

SIR,—When the syllabus of subjects for examination was first introduced by the General Nursing Council in 1922 a protest was made by the honorary staff of the Staffordshire General Infirmary in regard to the scope of that syllabus. This protest was disregarded at the meeting then held. Following the general approval of the scheme, however, the members of the staff responsible for lectures have diligently attempted to follow that syllabus in spirit and letter, with careful attention to that sentence in the preface which states, "The examination shall be of a simple and practical character."

In the Final State Examination papers are set on medicine and surgery apart from medical and surgical nursing. The papers for February 2nd, 1926, contained the following questions:

Describe the early symptoms of a case of typhoid.

What are the symptoms of gastric ulcer? From what other abdominal conditions has it to be diagnosed? Give points of distinction.

What is meant by retroversion? What symptoms does this cause, and how is it treated?

I may observe in regard to the third question, that retroversion and displacements of the uterus receive no mention in the syllabus.

I protest that such questions are unwarranted, that symptoms and differential diagnosis should not enter into

an examination on nursing. The matter is a serious one for small provincial hospitals. Candidates for nursing training are scarce, and the general standard of education among them is not high; they will disappear altogether if such an academic examination be insisted on. My experience is that many practical and useful trained nurses will be excluded from registration. The public and the medical profession require women well trained in practical nursing and the management of patients, not encyclopaedias of medicine and surgery.—I am, etc.,

E. J. BRADLEY,

Honorary Surgeon, Staffordshire General Infirmary.

Stafford, Feb. 6th.

Universities and Colleges.

UNIVERSITY OF CAMBRIDGE.

DR. R. D. GILLESPIE, resident medical officer of the Cassel Hospital for Functional Nervous Disorders, Panshurst, has been appointed to the Pinsent-Darwin Studentship in Mental Pathology at a stipend of £200 a year for three years. Dr. Gillespie was educated at the University of Glasgow, where he graduated M.B., Ch.B. in 1920 and M.D. with honours in 1924.

UNIVERSITY OF LONDON.

UNIVERSITY COLLEGE.

FOURTEEN entrance scholarships and exhibitions are available for award to students entering University College, London, in October, 1926. Three of them are tenable in any of the five College Faculties (Arts, Laws, Science, Engineering, and Medical Sciences) or in the School of Architecture. Two of them are tenable in the Faculty of Arts only, one in the Faculty of Science, one in the Faculty of Engineering, one in the Faculty of Laws, three in the Faculty of Medical Sciences, two in the School of Architecture, and one in the School of Librarianship. Most of the scholarships and exhibitions are of the value of £40 a year for three years, but the value of any scholarship or exhibition may be increased by the grant of a supplementary bursary if the circumstances of the scholar or exhibitor make such a grant necessary. Particulars of all these scholarships and exhibitions may be obtained from the Secretary, University College, Gower Street, W.C.1.

LONDON SCHOOL OF MEDICINE FOR WOMEN.

At a special meeting of the council held on February 4th Lady Barrett, C.B.E., M.D., M.S., was elected to the honorary office of Dean of the London (Royal Free Hospital) School of Medicine for Women.

UNIVERSITY OF BIRMINGHAM.

DR. WILLIAM H. WYNN, F.R.C.P., physician to the Birmingham General Hospital, has been appointed joint professor of medicine.

NATIONAL UNIVERSITY OF IRELAND.

THE Senate at its meeting on February 5th had under consideration the reports of the examiners upon the results of the pre-registration examination in physics and chemistry, December, 1925, and the M.B., B.Ch., B.A.O. degrees examination, January, 1926, and awarded passes, honours, etc., in connexion therewith.

The following appointments were made:—*University College, Dublin*: Lectureship in gynaecology, Reginald J. White, F.R.C.S.I.; lectureship in obstetrics, James J. O'Kelly, B.A., M.B., B.Ch., B.A.O. *University College, Cork*: Professorship of obstetrics and gynaecology, John J. Kearney, M.D., D.P.H.

The Services.

TERRITORIAL DECORATION.

THE KING has conferred the Territorial Decoration upon the following officers of the R.A.M.C., T.A., under the terms of the Royal Warrant of October 13th, 1920: Lieut.-Colonel William Archibald, Major Oskar Teichman, D.S.O., J.C.

DEATHS IN THE SERVICES.

Inspector-General Thomas Browne, R.N. (ret.), died at Weymouth on January 29th, aged 84. He was born in 1841, and educated at Queen's College, Belfast, where he graduated as M.D. with first class honours and gold medal in 1862, also taking the L.R.C.S.Ed. in the same year. Entering the navy as assistant surgeon in January, 1863, he reached the rank of Deputy Inspector-General in December, 1895, and of Inspector-General in July, 1899, retiring two months later. He served in the Naval Mental Hospital at Yarmouth from July, 1880, till February, 1894, for the greater part of the time in charge, and on his promotion to Deputy Inspector-General a petition was sent to the Admiralty asking that he might be allowed to retain charge of that hospital after promotion. As Deputy Inspector-General he served in charge of the Royal Naval Hospital at Bermuda from 1894 to 1897, and as second in command of the Royal Naval Hospital, Plymouth, from 1897 to 1899. He was a keen golfer, and is said to have been the introducer of the term "Colonel" Bogey for the par score. In 1871 he married Miss Agnes Robertson Dall, daughter of James Dall, J.P., of North Berwick, and leaves a widow, a son, and five daughters.

Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

HAVING completed the debate on the Address on Monday, the House of Commons spent the rest of this week considering Supplementary Estimates, and also topics brought forward by private members. A debate on Tuesday evening, February 9th, concerning unregistered medical practitioners was talked out after the Minister of Health had declared that he could not propose either the recognition of osteopaths and other unqualified practitioners or prohibition of practice by them. A lay member, Mr. Storry Deans, remarked that public confidence in the General Medical Council would be increased if it included laymen, and that this change could be achieved under the present law. This remark was understood to have been made at the direct suggestion of the Minister of Health. Although Mr. Chamberlain did not take it up in his reply, Professor T. Sinclair, as the only member of the General Medical Council in the House of Commons, said he believed his colleagues would have no objection to the Council being reinforced by lay members. In putting down his motion on unqualified practice Dr. Graham Little did not act for, or in consultation with, the Medical Committee of the House of Commons.

National Insurance.

It is hoped that the report of the Royal Commission on National Health Insurance will be available about the end of this month.

Colonial Medical Service.

On February 8th Mr. Amery informed Mr. Ramsden that he hoped shortly to be able to make a definite announcement regarding the appointment of a medical adviser in the Colonial Office.

Parliamentary Medical Committee.

At the first meeting of the Parliamentary Medical Committee for the session, on February 3rd, Dr. Fremantle was re-elected chairman of the group and Dr. Graham Little secretary. In accordance with a decision taken before the recess, the Committee arranged to hold an open meeting for Peers and members of Parliament in about a month's time at which the medical view would be expounded concerning the relations of the public, the medical profession, and the General Medical Council. The meeting also considered the Colonial Medical Services, and discussed criminal justice in its application to the effects of encephalitis lethargica. On this latter question action by the Committee was contemplated. A further subject of discussion was the proposed bill for the registration of opticians. The Committee arranged that at its next meeting it should discuss the Coroners Bill, the Births and Deaths Registration Bill, which the Government hopes to introduce in a new form, and a pamphlet on the imperial aspect of social hygiene, which has been distributed to members by the British Social Hygiene Council.

Unqualified Medical Practice.

On February 9th the question of unqualified medical practitioners was raised by Dr. Graham Little. He called attention to the spread of unqualified practice in medicine and surgery by osteopaths, chiropractors, and other irregular practitioners, and moved that an authoritative inquiry, with the object of making recommendations to Parliament for dealing with the whole position of irregular practice in medicine and surgery, was urgently necessary. Dr. Little said that the spread of unqualified medical practice must be admitted. The reasons were many, but the most important was the length of the medical curriculum. It was not true, as was sometimes represented, that British medicine was a system of knowledge confined to the British Islands and the British Empire; it was part of international medicine. It had one distinction—namely, that its students were taught with the interests of the patient always in view. An important quality of international medicine was that any discovery made by one individual was immediately made known to the rest of the world. The note of unqualified practice was the secrecy of the methods employed, and the absence of opportunities for clinical study.

Osteopaths were most in the public eye at the present time, and in many respects differed from the other groups of unqualified medical practitioners. They claimed to be as fully trained in medicine and surgery as were the ordinary students in our medical schools. But nine-tenths of their training was

received in the United States. Their system was based on a formula or theory propounded fifty years ago by an obscure medical practitioner in one of the small towns in the Western States of America. That theory had been examined and had been rejected by international medicine, and nowhere more thoroughly than in the United States. The British medical profession was not a close trade union which refused to admit any outsiders. Applicants from approved foreign colleges were allowed to sit for an examination set by the licensing authorities in this country without preliminary tests. Osteopaths were not allowed to hold commissions in the medical services of the United States naval and military forces. Osteopaths held that the treatment for ills was the manipulation of the bony structure of the body, and the theory that all disease arose in the spine, and might be helped by manipulating the spine, was the basis of osteopathy.

The five great scourges of the modern world (Dr. Little continued) were tubercle, syphilis, malaria, cancer, and insanity. Three out of five of those diseases were regarded by all the world, except, perhaps, the osteopaths, as being due to bacterial effects. The germs which caused these diseases could be seen under the microscope. In the case of cancer modern work pointed to a bacteriological form, direct or indirect, and a very large number of cases of insanity were unquestionably due to bacterial effects. In cases of tuberculosis the damage was greatly increased by the manipulation of tuberculous joints. No one could have held, as he had for nearly thirty years, the position of a hospital physician without being saddened by the cases that one saw of the terrible neglect of the poor through unqualified medical treatment. In this remark he referred to the dispensing chemist, the optician who pretended to be an oculist, and the quack dentist who fitted new plates upon septic stumps. With the exception of England, Germany, and five of the Australian States, practically all the countries of the civilized world penalized unqualified practice. For that reason he asked for an inquiry.

Mr. Hilton Young, who seconded, said the resolution was not aimed against any particular theory of the practice of medicine. They were entitled to say that a man should not carry his goods and sell them to the public under something like a Government guarantee unless he had taken the trouble properly to qualify himself.

Mr. Atkinson moved an amendment to provide that the object of the inquiry should be to secure the recognition and registration of manipulative practitioners having approved qualifications. The committee of inquiry could settle what the necessary qualifications should be. In America there were seven colleges under the American Osteopathic Association. The standard set there was high. There were hospitals and sanatoriums working in America under the same supervision, and their work was done efficiently and well. Progress had not been made in this country because of the opposition of the medical profession. They were all familiar with the notorious case of Dr. Axham, who was hounded out of his profession because he administered chloroform for a most able manipulator. Osteopathy was a branch of knowledge which did not form part of the medical curriculum. The ideal way would be for the medical profession in this country to bring it within the medical curriculum, and then persons who showed special skill in that branch could specialize.

Mr. Basil Peto, in seconding the amendment, said that what the mover of the motion wanted was, not to set up an impartial committee to inquire into a question of public interest, but to have an inquisition into these irregular practitioners, which would be able to pronounce a sort of anathema against the whole of them, including Sir H. Barker. Dr. Graham Little, interposing, said that his words would not bear that meaning. Mr. Peto said Dr. Little had referred to the penalties imposed in other countries. What the House was interested in was that humanity should have the advantage of every fresh discovery in the art of healing.

Mr. Storry Deans said a good deal of the public unrest about this question had been caused because the public had lost faith in the General Medical Council. The General Medical Council had become something very like the executive of a trade union, and it had acted in the trade union interests of its members instead of acting solely in the interests of the public. He suggested that the Minister of Health should use his influence or his power to place the General Medical Council in the position which it was intended to occupy—that was to say, it should consist mainly of medical men, but it should also contain a lay element, representing especially the interests of the public. This could be done under the existing Act.

Dr. Drummond Shiels thought an inquiry such as Dr. Little desired was not necessary at the present time. At the same time some observation required to be kept on unqualified practice. He objected still more to the terms of the amendment. While the medical profession had derived advantages from contributions of outsiders there was a limit to the extent to which unorthodox practice should be permitted, and that

limit was the safety of the public. The bulk of the medical profession would be prepared to admit that Sir Herbert Barker had performed considerable services, and that he was a man of no mean skill. But he was exceptional. Bone-setting formed a small part of medicine and surgery, and a general diploma was quite impossible in a case like that. The medical profession did not object to osteopathy being practised, but they said that before any man should get a qualification to practise medicine or surgery on any system he ought to have a definite minimum of fundamental medical knowledge. The present medical curriculum gave the minimum that was necessary for the practice of any system of medicine. That minimum they believed the osteopathic colleges did not give at present. The mover of the amendment had recited a number of cures which had been effected by osteopaths. In any system of medicine they could get a list of wonderful cures. He also could bring a list of cases where the results of treatment by osteopaths had been disastrous, both in this country and America. He agreed that doctors also made mistakes. Nowadays everyone had a smattering of health knowledge and a certain amount of technical knowledge. The remarkable fact was, not that the General Medical Council had been so much criticized, but that, on the whole, it had emerged from this criticism so successfully. The Council had suffered from lack of publicity as to its doings. The Council gave a much fairer and more careful trial in its penal cases than the public knew. It was no pleasure to the members of the Council to strike any man off the *Medical Register*, and it was only done in the public interest, because the Council was a body set up to look at the profession from that point of view.

Mr. Bromley expressed the fear that notwithstanding its innocuous appearance the resolution implied a heresy hunt. He opposed it because of the possible danger that the lay mind might be overridden by the Latin jargon of the medical profession.

The Minister of Health (Mr. Neville Chamberlain) did not think the dangers of unqualified practice could be denied. There was the positive danger of actual harm being done by too violent treatment, or by the administration of harmful drugs. Indirect harm might also be done by inducing a patient to seek unqualified assistance, and consequently postponing application to a man who really could cure him until the disease had gone too far. Mr. Chamberlain asked whether Dr. Little desired total prohibition of irregular practitioners. The public was, however, growing more educated and more fitted to discriminate between the trained and the ignorant man. His view was that they did not wish to cut themselves off from being able to profit from the skill of any man, provided it was understood that they consulted him at their own risk. He would not advise the House to accept Dr. Little's motion as it stood on the paper, nor the amendment of Mr. Atkinson. That amendment suggested the recognition and registration of osteopaths, which would be taken by the public as a guarantee of some kind, though it would not be. Mr. Atkinson had asked the House to support the recognition of osteopaths having approved qualifications. He had not said what these qualifications should be, but had talked instead about skill. How could a nation lay down rules for the testing of skill? They would have to fall back on diplomas given by American colleges, diplomas into the value of which they could not examine, and colleges over whose qualifications they had no control. That was not practicable.

Mr. Peto said his friends wished to set up an osteopathic college in this country and not to have importations from America.

Mr. Chamberlain, continuing, said that manipulative surgery was already taught in the curriculum of the General Medical Council, and any medical man could specialize in it. Some of the most celebrated had done so. He was glad to hear from Mr. Peto that the osteopaths did not desire the recognition of American colleges. He knew nothing to prevent the osteopaths setting up their own colleges and giving their own diplomas. That, he thought, was the only way for them to achieve recognition. They would then be forced to do what had been done in America. Their curriculum would gradually have to approach to the normal, and the more near that approach the easier it might be to set up a register. He thought he had indicated a direction in which progress could be made. He did not think it was necessary to prohibit, and he did not think public opinion would be in favour of prohibiting, unqualified practice. But the proposals of the amendment seemed impossible to defend, and on the whole he thought the House would do best to leave things to develop in their own normal fashion.

Professor T. Sinclair said he was the only member of the House who was also a member of the General Medical Council. That Council did not proceed against osteopaths. It could not consider their registration, as it had no means of inspecting their schools, which were in America. He held that it was in

the public interest that they should ascertain what persons were entitled to practise surgery in view of the danger of unqualified manipulative surgery in cases unsuited for rough handling. A demand had been made that night that the General Medical Council should be reinforced by lay members. Speaking for himself, he did not object to this, nor did he believe his colleagues on the Council objected. Machinery existed already for making the change. The Privy Council could use its powers of nomination to place lay representatives on the Council, and the universities could also send lay representatives. The reasons why they had not lay representatives were that three-fourths of the work of the Council dealt with medical education and registration, and people could not be got to take a sustained interest in the regulations for the curriculum and examinations unless they were medical men.

The motion was talked out, neither it nor the amendment being put to the House.

Encephalitis Lethargica.

Replying to Mr. Ammon, the Home Secretary, Sir William Joynson-Hicks, said his attention had been called to the case of a youth suffering from the after-effects of encephalitis lethargica when the lad was in prison on remand, having been charged at Lambeth Police Court with stealing a shilling. He had asked the Medical Commissioner of Prisons to attend at the court and give the magistrate a full account of the examination made by the prison doctors. The lad was released on probation, and his future welfare was receiving careful attention. Courts had wide powers of dealing with persons who were certifiable under the Mental Deficiency Act, but persons whose morale had been affected by encephalitis lethargica might not be certifiable either under that Act or under the Lunacy Acts. The problem raised by these cases was receiving the attention of the Minister of Health in consultation with the Home Office.

In a further reply to Mr. Ammon, the Home Secretary said he had obtained a special report concerning the prisoner certified on medical authority to be suffering from brain trouble, who was at the Old Bailey, on January 19th, sentenced to twelve months' hard labour. Sir William declared that, on the information before him, he had no grounds for believing that the sentence passed on this man was other than appropriate. Mr. Ammon asked whether the Home Secretary noted the wish expressed by the Recorder in passing sentence that Parliament would give the judges power to send certain offenders who were not insane to places, other than prisons, where they could receive more expert treatment. Sir William Joynson-Hicks said he would give this suggestion most careful consideration. He realized there was a difficulty in this class of case. This particular prisoner was in good physical and mental health, and showed no sign of organic disease.

Mr. Chamberlain told Mr. Trevelyan Thomson that he could not give particulars of the vaccinal condition of persons suffering from encephalitis lethargica during any recent period.

Mental Deficiency.

Mr. Erskine asked the Minister of Health whether, in view of the increasing numbers of mentally deficient persons in the country, he would set up a committee to inquire into and report on the best means of dealing with the problem, whether by sterilization or otherwise. Mr. Chamberlain replied that the incidence of mental defect was being investigated by an expert committee of representatives of the Board of Education, the Board of Control, and others. He would carefully consider Mr. Erskine's suggestion, but was not in a position to give any undertaking.

The Minister for Education (Lord Eustace Percy) said he had asked the Leyton education authority to postpone its scheme for providing a special school for mentally deficient children. Postponement was until the Minister had before him the revised estimates of local authorities for the coming year. At the present moment he was not, in general, giving final approval to new schemes for the building of schools for defective children.

Bills.

Dr. Fremantle proposes, with the concurrence of the Ministry of Health, to introduce a Midwives and Maternity Homes Bill, to amend the Midwives Acts, 1902 and 1918, and to provide for the registration of maternity homes and for purposes connected therewith.

In view of the pressure of other business the Minister of Health is not prepared to consider the introduction of a bill to prevent unqualified persons from practising as optical specialists.

A bill to amend the Blind Persons Act, 1920, has been presented by Mr. Lee, and received a first reading.

The Home Secretary, in an answer to Mr. Robinson, said the Government did not propose to proceed with the Factories Bill during the present session, but intended that it should pass during the present Parliament. Mr. Betlington (Parliamentary Secretary to the Ministry of Labour) said that until agreement for the regulation of hours of labour the British Government could not decide whether it would introduce a bill ratifying the Washington Convention for the eight hours day.

The Minister of Health informed Mr. Campbell that he hoped a Smoke Abatement Bill would be introduced in the House of Lords at an early date.

Small-pox in County Durham.—On February 8th the adjournment of the House was moved to discuss the condition of miners in county Durham, who, being involved in a trade dispute, had been refused unemployment benefit and poor relief. Mr. Batey said an epidemic of small-pox had broken out in Durham, but it did not occur until the men became impoverished. Now there were 700 cases of small-pox in the district. He complained of the action of the Ministers of Mines, Health, and Labour in refusing relief and benefit. Mr. Lawson said that in the immediate neighbourhood of Consett, where unemployment was general, small-pox resulting from the stinting of food and clothing had got out of the hands of the local authorities and threatened not only Durham but the country. He heard last week that the ordinary disease, as they had known it for a few months, had gone, and that now the most dreadful type was breaking out. Mr. Neville Chamberlain (Minister of Health) said there was not a shadow of evidence that the spread of small-pox was connected with the refusal of the guardians to give relief. On the other hand, it was well known that a large proportion of the people in this district were unprotected by vaccination, and, further, that there was insufficient isolation hospital accommodation in the district. There was one further circumstance, which he need not mention then, to which they might probably attribute the spread of small-pox. He had been bound to refuse a further loan to the local board of guardians after they had exhausted their financial resources, because, under the Merthyr Tydfil judgement, it was illegal for the guardians to give relief to these men. The Prime Minister said he was anxious for a satisfactory settlement of the industrial dispute, and he had every hope that it would be settled.

Miner's Phthisis.—Colonel Lane-Fox (Secretary, Mines Department) told Mr. D. Grenfell that an inquiry had been completed into the incidence of miner's phthisis among men engaged in rock-boring with compressed-air machines in coal mines. The inquiry supported the view that in certain rare conditions dry rock-drilling might be dangerous. As a result, preventive measures had been suggested, and the mines inspectors were dealing with the question of their adoption. Medical inquiry was also proceeding to ascertain whether the disease had, in fact, been caused in the places where dangerous conditions had been found. On February 9th Mr. C. Edwards asked the Secretary for Mines if he was aware of the number of men in mines suffering from the effects of stone-dust, that medical men were certifying the disease, and that these cases were rapidly increasing. Colonel Lane-Fox replied that it was in rare and exceptional cases of dry drilling in siliceous rock that men were exposed to danger. He had no evidence that the number of men affected was increasing.

Birth Control.—In the House of Commons, on February 9th, Mr. Thurtle asked leave to present a bill to authorize local authorities to incur expenditure, when deemed expedient, in conveying knowledge of birth-control methods to married women who desired it. He said the fall of the birth rate became more and more marked in the upper and middle classes, while among the poorer people it was almost stationary. In Westminster the birth rate was 11.2 per 1,000, in Shoreditch 25 per 1,000, and in Chelsea 14.3 per 1,000. In districts where overcrowding was rampant and poverty acute there was a very high birth rate. The bill would throw no charge on the national exchequer, and was merely permissive. The nation was expending money in broadcasting information about sanitation, personal hygiene, diet, tuberculosis, and venereal disease, and there was not a phase in that work which was not rendered more difficult by the fact that in the poorest districts women were having larger families than were good, either for themselves or for the State. The Rev. J. Barr, the Labour member for Motherwell, opposed the introduction of the bill. Leave to bring in the bill was refused by 167 votes to 81.

Staff of the Ministry of Health.—Answering Mr. Briant, Mr. Neville Chamberlain said all posts in the Ministry of Health were open to both sexes with the exception of certain higher posts on the outdoor insurance staff, where at present there were separate establishments for men and women, with higher posts for each. This organization would shortly be reviewed.

Spectacles for Insured Persons.—Mr. Chamberlain stated, in reply to Mr. Rhys Davies, that he had not received any general representations with regard to excessive charges made by opticians for examinations and supply of glasses to insured persons as additional benefits under Section 75 of the National Health Insurance Act. The schemes that became operative in July last following the second valuations enabled an approved society to restrict the cost to its own funds in respect of appliances to such charges as were reasonable. The general question of the power of the Central Department to supervise the provision of this and other additional benefits in the nature of treatment had received the consideration of the Royal Commission on National Health Insurance.

Nursing Homes.—On February 8th Sir Kingsley Wood, Parliamentary Secretary to the Ministry of Health, replying to Mr. G. Hurst, who asked if he intended this session to appoint a committee to inquire into the desirability of legislation with regard to the registration of nursing homes, said that in accordance with the undertaking given by the Parliamentary Under Secretary for Health for Scotland, on June 19th last, steps were being taken for the appointment of a select committee to inquire into this question.

The Fighting Services and Special Appeal Tribunals.—Mr. Bridgeman, First Lord of the Admiralty, replying, on February 8th, to Sir B. Falle, said that in the opinion of the three fighting services the cost of a special appeal tribunal for men invalided

from service would not be justified generally in view of the full medical records available and the stringent medical examination on entry and the fact that there was a right of appeal to the Board of Admiralty. He was, however, considering whether an exception to the general rule might not be possible in certain specific cases.

Driving Licences.—On February 8th the Minister of Transport (Colonel Ashley) stated that he had the general question of the issue of driving licences to persons suffering from physical disabilities under consideration in connexion with the bill for the better regulation of road vehicles, which was referred to in the King's Speech.

Notes in Brief.

The Minister of Health is compiling, and will circulate, statistics giving the number of hospitals provided or aided by local authorities in England and Wales, and the number of maternity, tuberculosis, infectious diseases, and other hospitals.

A complaint regarding Croydon Corporation sewage farm at Mitcham Common is being investigated by the Ministry of Health.

For the guidance of sanitary authorities a revised code of model by-laws regulating the conditions of hop-pickers has been prepared by the Minister of Health, who is conferring with the Minister of Agriculture concerning them.

The Secretary for War regrets that it will not be possible to suspend for as long as six months the order for ejection of the occupants of dwelling-houses at St. Helens contiguous to a Government poison-gas factory.

In 1924 insurance companies doing workmen's compensation business in Great Britain received £5,532,459 in premiums and paid £2,903,159 under policies, the latter sum including legal and medical expenses in connexion with claims.

Less than 1 per cent. of recruits to the Royal Air Force were discharged within twelve months of acceptance for physical or mental disability.

Earl Winterton states that the expenditure out of Indian revenue for medical services was £2,081,896 in 1921-22, £2,055,681 in 1922-23, and £2,163,274 in 1923-24. In the same years the expenditure on public health was £1,042,535, £754,424, and £792,779 respectively.

It is estimated that during the five months ending January 31st about 8,600 cows have been slaughtered under the Tuberculosis Order of 1925.

The original estimates for 1925-26 for public health, unemployment insurance, and housing amounted to £32,417,000, representing a cost per head of the population of 14s. 8½d.

The Home Secretary is giving consideration to the report of the departmental committee on sexual offences against young persons, but will not propose legislation till he has also received a forthcoming report on the treatment of youthful offenders.

Experiments on the efficiency of various poison gases are still being carried out by the War Office.

Obituary.

We regret to announce the death of Mr. SIDNEY ELLIS of Salisbury, who died on January 25th from influenza and double pneumonia. He was a native of Binsted, near Arundel, and started his professional life at the early age of 16 as apprentice to the late Dr. Evershed, a well known hunting practitioner of that district who kept a large stable of horses. He received his medical training at King's College Hospital, and after obtaining the M.R.C.S. Eng. and L.S.A. diplomas in 1883 he became medical registrar of the Seamen's Hospital, Greenwich. Later, while assisting the late Mr. Ensor of Tisbury, he became acquainted with his wife, the daughter of Mr. G. Smith, coroner for Salisbury and secretary to the infirmary, and this led to his taking in 1893, after practising at Culmstock, Devon, the practice of the late Dr. Gordon of Salisbury, which included two Poor Law appointments, one for the city and one for the country district of Winterslow. Mr. Ellis was also a public vaccinator, one of the medical officers of the Provident Dispensary, and he had a large number of club and panel patients. This, in addition to his private practice, meant a very arduous life, which, together with the death of his wife after a long illness, undoubtedly affected his health. A colleague writes: Mr. Ellis worked very hard for the good of his poorer patients, and the widespread regret at the loss of "our doctor," so touchingly expressed by them, has indeed testified to his place in their hearts. He was a keen and good cricketer, playing for his hospital, and at Salisbury for South Wilts and local clubs. He was one of a small number of friends, lately entirely medical, who for many years met weekly, first for whist and then for bridge, when many things were talked over and much cheerful chaffing done; the gap is very much felt. It was at one of these gatherings just before his illness that he was telling us of an anxious and probably

irate husband dragging him, a 16-year-old apprentice, and the dispenser to attend his wife at her confinement, Dr. Evershed being away. He also had very interesting stories of the superstitions, medical and otherwise, of his Devonshire practice. He was a member of the British Medical Association, and represented the local Division on the committee of management of Salisbury General Infirmary.

DONALD MACRITCHIE, who died at Huntingdon on January 28th, after a short illness, at the age of 71, received his medical education in Aberdeen and Edinburgh. He graduated M.B., C.M.Aberd. in 1875, and obtained the L.R.C.S. and L.M.Edin. in 1876. After holding the post of assistant medical officer to the Royal Asylum, Aberdeen, he came south in 1877 and was appointed house-surgeon at the County Hospital, Huntingdon. There he remained until 1880, when he resigned to join Dr. Ballard in the county town. He was in the same year elected honorary surgeon to the County Hospital, a position he held until his death. His life was entirely devoted to his practice and the hospital, where he was to be found at stated times with unfailing regularity. To the hospital his loss will be very great, for he was ever at hand to advise and to undertake responsibility for action in the absence of his colleagues. A colleague writes: He was a man of wide experience, ripe judgement, acute observation, and practical shrewdness in rare combination. His patients will miss a true friend, counsellor, and a genuine sympathizer with them in their troubles. As a member of the British Medical Association his retiring nature made him unwilling to accept the publicity of the highest honour the local Branch wished to confer upon him.

The funeral service for the late Mr. CHARLES P. CHILDE, F.R.C.S., Past-President of the British Medical Association, who died at Monte Carlo on January 30th, was held in St. Jude's Church, Southsea, on Wednesday, February 10th, at noon, and the interment followed at Highland Road Cemetery. The Council of the British Medical Association was represented by Dr. David Ewart, O.B.E., of Chichester, and the headquarters staff by Dr. C. Courtenay Lord, Assistant Medical Secretary.

Medical News.

THE chairman, H.R.H. Prince Arthur of Connaught, and the Board of the Middlesex Hospital, have issued invitations to the opening of the hospital annexe to be performed on Tuesday, February 23rd, at 3.30 p.m., by the Right Hon. Neville Chamberlain, M.P., Minister of Health.

THE trustees of the Will Edmonds Clinical Research Fund invite applications for a Fellowship. The salary is £500 per annum, and the holder is eligible for annual re-election up to five years. The successful candidate will be required to devote his whole time to research in a metropolitan hospital. Applications must be sent to the honorary secretary of the Fund, 68, Great Cumberland Place, London, W.1, on or before February 27th.

A COURSE of three lectures on some principles of therapeutics will be given by Professor D. Murray Lyon (Edinburgh) at St. Thomas's Hospital Medical School, Albert Embankment, S.E.1, on February 22nd, 23rd, and 24th at 5.30 p.m. Professor H. Maclean will take the chair at the first lecture. Admission to the lectures is free.

THE Fellowship of Medicine announces that on February 18th a lecture on artificial pneumothorax as a means of treating pulmonary tuberculosis will be given by Dr. R. A. Young at 11, Chandos Street, at 5 p.m.; this lecture is free to all members of the medical profession. Mr. J. Swift Joly will hold a special clinical surgery demonstration at 2 p.m. at St. Peter's Hospital, on February 17th, for members of the Fellowship or holders of its general course tickets. Beginning on February 15th, the Queen Mary's Hospital, Stratford, will hold a fortnight's course in general medicine and surgery, from 10 a.m. until 5 p.m. daily, except Mondays, when the sessions start at noon. During the first fortnight in March at the Royal Eye Hospital there will be a special course in ophthalmology, with clinical demonstrations each afternoon from Monday to Friday inclusive. During the early part of March also, the Westminster Hospital will arrange a special course in bacteriology. The Chelsea Hospital for Women

will give a course in gynaecology occupying the last three weeks of March, consisting of operations, lectures, and demonstrations, and during the last fortnight the Brompton Hospital will hold an all-day course in diseases of the chest. From March 15th to 27th there will be a daily course in general medicine and surgery at the Hampstead General Hospital from 4.30 to 6 p.m. for general practitioners. A course in tropical medicine, consisting of two sessions weekly at the London School of Tropical Medicine, will begin on March 16th. Copies of all syllabuses and of the general course programme may be had from the Secretary of the Fellowship of Medicine, 1, Wimpole Street, W.1.

A MEETING of the Society of Medical Officers of Health will be held in Glasgow on February 19th, at 2.30 p.m. The agenda includes a discussion on heart disease from the points of view of public health administration, the physician, the school medical officer, and the factory surgeon. Dr. J. J. Buchan will read a paper on his experience at Bradford of the new notification clauses with regard to venereal disease. A portrait of Dr. Chalmers, president of the society from 1913 to 1914, will be presented by the Scottish branch. Members attending the meeting will be entertained at luncheon by the Provost and Corporation of Glasgow, and those proposing to be present are asked to notify Dr. A. S. M. Macgregor, Sanitary Chambers, Glasgow, as soon as possible.

THE public health section of the College of Nursing has arranged a post-graduate course from April 1st to 15th. The first week will include classes in anatomy, physiology, hygiene, and sanitary law, and during the second week lectures will be given on Poor Law reform, State insurance, heliotherapy, diseases of early infancy, and similar subjects. Either week may be taken separately if desired, and it is stated that grants are obtainable from the local authorities towards the expenses of the nurses attending both courses.

A CLEAN milk and food exhibition organized by the Medical Officer's Department of the Borough of Hornsey will be held at Christ Church Hall, Edison Road, Crouch End, from March 2nd to 5th. It will be opened by the Right Hon. Neville Chamberlain, M.P., Minister of Health, at 2.30 p.m. on Tuesday, March 2nd.

A MEETING of the Central Midwives Board for England and Wales was held on February 4th, with Sir Francis Champneys, Bt., in the chair. The ordinary meeting was preceded by a penal session. It was announced that Sir Francis Champneys, Dr. R. A. Lyster, Mr. L. H. West, and Mrs. Bruce Richmond had been re-elected to the Board. Drs. Florence Bentham and Arthur R. Lister were approved as lecturers, and approval as a training school was granted to the Norwich Union Infirmary. It was stated that the training of pupil midwives had been discontinued at Islington Infirmary. Approval as teachers was granted to two applicants.

A COURSE in dermatology will be held at the Hôpital Saint-Louis in Paris, from April 12th to May 16th, followed by one in venereology from May 17th to June 11th, and another in therapeutics from June 14th to July 2nd. Throughout this period there will also be a course in laboratory technique. Further information may be obtained from Dr. Burnier, Hôpital Saint-Louis (Pavillon Bazin). The fee for each course is 250 francs.

THE Académie de Médecine of Paris has awarded the Buisson prize of 12,000 francs to Dr. Levaditi for his work on bismuth in the treatment of syphilis.

THE *Journal de Médecine de Bordeaux et du Sud-Ouest* for November 25th, 1925, contains a facsimile of the cover of the *Journal Médical de la Gironde*, which, as we stated in our issue of January 23rd (p. 174), was the original title of the journal.

THE following professors have recently been nominated in the French Faculties of Medicine: Dr. Pierret (chair of hygiene and bacteriology at Lille), Dr. Lafforgue (chair of hygiene and preventive medicine at Toulouse), M. Chaîne (chair of comparative anatomy and embryology at Bordeaux), and Dr. Baylac (chair of children's diseases at Toulouse). Dr. Rathery has been elected professor of experimental pathology, and Dr. Lemierre professor of bacteriology, in the Paris Faculty of Medicine, and Dr. Leblanc has been nominated professor of clinical surgery at the Algiers Faculty of Medicine.

PROFESSOR GARRÉ, director of the surgical clinic at Bonn, and Professor Minkowski, director of the medical clinic at Breslau, will retire on April 1st.

DURING 1925 Sao Paulo, Brazil, suffered from the severest epidemic of typhoid fever known in its history; 1,343 cases with 287 deaths were notified between December 1st, 1924, and May 31st, 1925.

ACCORDING to official investigations the number of dentists and midwives in Japan at the end of 1923 was 8,771 and 39,515 respectively—equivalent to 1.50 per 10,000 of the population of the former and 6.76 of the latter.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the **BRITISH MEDICAL JOURNAL** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the **BRITISH MEDICAL JOURNAL** must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the **JOURNAL**, should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBERS** of the British Medical Association and the **BRITISH MEDICAL JOURNAL** are **MUSEUM 9861, 9862, 9863, and 9864** (internal exchange, four lines).

The **TELEGRAPHIC ADDRESSES** are:

EDITOR of the **BRITISH MEDICAL JOURNAL**, *Aitiology Westcent, London.*

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate Westcent, London.*

MEDICAL SECRETARY, *Mediscera Westcent, London.*

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 4361 Central).

QUERIES AND ANSWERS.

CLIMATE.

"BOURNEMOUTHIAN."—There is no really dry warm climate in England. Our correspondent might compare the climatic data of his district with those of other English climatic resorts in Edgar Hawkins's *Medical Climatology of England and Wales*, London, 1923. Sidmouth, Budleigh Salterton, and Torquay might be thought of.

"M. K. H.," who desires a place on the Eastern Riviera for an all-the-year-round residence for a middle-aged man with bronchial trouble, might consider Nervi (closely connected with Genoa) and Viareggio (thirteen miles from Pisa). We published in the **JOURNAL** of January 20th, 1923 (p. 116), a short article on the Italian Riviera. Further particulars can, we believe, be obtained from the tourist office of the Italian State Railways, 12, Waterloo Place, Regent Street, S.W.1.

ARSENICAL DERMATITIS IN SYPHILIS.

"F. M." asks for advice as to the point he raises at the end of his account of the following case. A man of 48 has syphilitic ulcers on right leg of several months' duration; he is a garage proprietor, and is very anxious not to lie up. Eight months ago I gave him six injections of N.A.B. and the ulcers became much smaller, although he did not rest, but after the fourth injection (0.45 gram) he complained that he had had severe itching of his feet; after the fifth he had blisters on his feet and itching for two nights; after the 6th (0.6 gram) red miliary papules appeared, extremely irritable on wrists and feet; temperature 99°; lasted two days. I then waited a month and gave another dose of 0.6 gram, which was followed by severe reaction as before. I then decided to substitute Silbersalvarsan, and gave one dose of 0.1 and four of 0.2 gram, but the ulcers did not improve; he was taking mercury and iodides all the time; he was also given three intramuscular doses of bismuth salicylate. Is it safe to try N.A.B. again by itself or mixed with sodium hypsulphite solution?

WANTED—A CHILD.

"PUZZLED" asks for helpful suggestions in the following case in which the patient is very anxious to have a living child. Her first pregnancy at seven and a half calendar months was complicated by placenta praevia and a transverse presentation. Caesarean section was performed and the mother made an uneventful recovery. Her second pregnancy, three years later, miscarried at eight calendar months; the child was dead, but the foetal heart had been heard two weeks previously. The patient is an apparently healthy woman, aged 26; her Wassermann reaction is negative. There has been no albuminuria during pregnancy; the blood pressure is normal, and the uterus and appendages are healthy.

INCOME TAX.

Car Depreciation.

"S. M. I." bought a car in 1920 for £560 and replaced it in 1923 by another car of higher power for £555, receiving £180 for the original car. What allowances is he entitled to?

(1) As an expense of replacement as incurred in the year 1923, £555—£180=£375. In our view to base the allowance on the

1923 cost of the original car is in opposition to the evidence given before the Royal Commission by the present Chairman of the Board of Inland Revenue. (2) By way of depreciation allowance for the financial year 1925-26, say 20 per cent. on the £555 as written down by one year's depreciation—that is, 20 per cent. of 80 per cent. of £555=£88. It is true that "S. M. I." for the time drops one year's depreciation, but when the present car is renewed he can claim the cost of renewal as a professional expense provided he treats the total of the allowances received as deductible from the net renewal cost; he will then be recouped for the fact that he has had no allowance for the financial year 1924-25.

Allowance for Student Son.

"J. W. B." has claimed relief in respect of his son, who is a student, aged 19, at a London hospital; his claim has been refused on the ground that "attendance at a medical school cannot be taken as in the nature of general education."

* * The statute does not speak of "general" education, and we are of opinion that the allowance can properly be given—in many instances it is given—in respect of a student at a recognized hospital course of training. We suggest that "J. W. B." might ask the local inspector to inquire of headquarters on the point, or alternatively that he should himself put the case in writing to the Secretary, Board of Inland Revenue, Somerset House.

LETTERS, NOTES, ETC.

VITAMIN DEFICIENCY.

DR. S. HENNING BELFRAGE (London, W.) writes: Your leader on this subject (February 6th, p. 250) cannot fail to arouse widespread interest and attention. It is to be hoped that the medical profession will now speak with less uncertainty and greater unanimity than heretofore on this long-debated question of the use of whole meal as opposed to white flour. Not a few authoritative pronouncements on this subject have hitherto been either half-hearted or definitely at variance. The economic difficulties can only be solved in one way—namely, by the education of the consumer to a realization of the extreme importance of a radical change in the existing preference for white as opposed to whole wheat flour. Such education can only be given by the medical profession, and no facilities for carrying it out must be denied to those whose obligation and privilege it is to educate the public in all matters concerning the maintenance of health and the avoidance of disease. Once the demand is created means will be found to ensure the supply. I was informed recently by one of the largest bread caterers in London that they have for some time past demanded from their millers that no wheat which had been subjected to the use of preservatives or bleaching agents should be supplied to them, and they have experienced no difficulty in obtaining the untreated article. In their opinion there would be no greater difficulty in obtaining whole wheat flour if, in response to a demand from the public, they wished to obtain and supply it. The facts are sufficiently well established without any further research work to enable the medical profession to act energetically and unanimously in furthering the interests of the health of the community by advocating this all-important change in its dietary habits.

A FAULTY GERMAN LEG.

IN the *Münchener medizinische Wochenschrift* for January 29th Dr. E. Schilcher describes a light prosthesis for thigh amputations, for which he claims the advantages of lightness, security from falls, and cheapness.

As Dr. Schilcher describes the usual artificial limb with movable knee-joint as weighing from 7 to 10 German pounds, or 7½ to 11 lb. *avoidupois*, it is evident that he is not familiar with the light metal limbs supplied by the British Ministry of Pensions, which are as light as Dr. Schilcher's prosthesis. The limb which he describes has a rigid knee for walking, with a lock-joint to be used for sitting only. It has a toe-joint, but no ankle-joint. Thus it will appear that it compromises between the peg-leg and in this country such-like limbs are certain manifest advantages, very few amputees are content to go about with a locked knee when once they have mastered the management of a well fitted and balanced metal limb with a movable knee-joint. Those who are content with a stiff knee would probably prefer to have the simple and light peg rather than a hybrid limb such as Dr. Schilcher describes. The Beaufort limb, which is also a compromise, has never been popular in this country. From the remarks of the author of the article as to the weight and qualities of the artificial limbs in use in Germany, we are inclined to conclude that the British limb-maker has little, if anything, to learn from Munich.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 41, 42, 43, 46, and 47 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 44 and 45.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 59.

The Hugh Owen Thomas Lecture ON THE ORTHOPAEDIC ASPECTS OF CHRONIC ARTHRITIS.

DELIVERED BEFORE THE LIVERPOOL MEDICAL INSTITUTION
BY

ROBERT B. OSGOOD, M.D.,

JOHN B. AND BUCKMINSTER BROWN PROFESSOR OF ORTHOPAEDIC SURGERY,
HARVARD UNIVERSITY.

At the outset I wish to express my admiration for the qualities of mind and heart possessed by the great character in whose memory this lectureship has been founded, and to acknowledge the debt of gratitude and affection which I owe to his successor and my orthopaedic master, Sir Robert Jones.

The subject of the orthopaedic aspects of chronic non-tuberculous arthritis has been chosen, first, because chronic joint disease merits all the attention which may be directed toward it; secondly, because there are certain aspects of these widespread and crippling affections which, in respect to functional treatment, come within the purview of orthopaedic surgery; and thirdly, because these conditions have been of almost chief concern to the immediate group of professional associates with whom my pleasant lot has been cast. I would emphasize the clinical nature of our discussion, disclaiming at the outset any significant share in the experimental or laboratory investigation which has clarified our conception of these diseases or types of disease, and which we earnestly hope will eventually make our treatment less empirical and more rational.

We still, in many cases, lack conclusive proof of the specific nature of the infections, if indeed they be infections, which draw the first strokes of clinical pictures eventually very similar. We still lack accurate knowledge of the abnormal physiological processes and biochemical derangements which as primary factors initiate, or as secondary factors prolong, the symptom-complexes with which we are familiar. Therefore, while we recognize the importance of placing the

emphasis upon investigation and not upon therapy, we shall strive to rationalize the knowledge of the morbid processes which we possess and apply this knowledge to a functional therapy.

NOMENCLATURE.

Let us not fall into the still common error of thinking of all cases of deforming arthritis as representing different manifestations of the same diseases, protecting our diagnostic heads by the shelter of the impressive name of "arthritis deformans." Even if we are convinced that there is a common etiological factor—infection, we must recognize at least two clinical types, running so true to form and exhibiting such distinct characteristics that they demand a separate nomenclature. Since no entirely satisfactorily descriptive terminology has yet been suggested, I direct your attention to Table I, in which, under headings of the commonly understood terminology of rheumatoid arthritis and osteo-arthritis, a few of the more important attempts at classification have been synonymized. Goldthwait and Swaim, my co-workers, believe that the rheumatoid type should be subdivided into those which are probably due to a specific infection which they call "infectious arthritis," and those in which atrophic bone and joint and muscle changes occur very early, seemingly not wholly dependent upon disuse, and suggesting a real but undefined neurotrophic factor. This form they designate as "atrophic arthritis." Strangeways¹ has recognized pathologically seven types of arthritis, which are often included in Great Britain under the name of "rheumatoid arthritis." I also direct your attention to Table II, in which the main contrasting differences in the two types are briefly recorded.

RHEUMATOID ARTHRITIS.

Etiology.

To most investigators at first sight no etiologic theory seems so probable as the infectious theory. Many investigators, after carefully reviewing the evidence, still believe that this theory offers the most attractive and hopeful explanation of the pathologic findings and the clinical pictures. We know that a chronic Neisser infection may be associated with a chronic polyarticular affection in which the joint tissue changes are fairly typical of rheumatoid

TABLE II.—*Differential Diagnosis.*

	RHEUMATOID ARTHRITIS.	OSTEO-ARTHRITIS.
Age incidence:	Infancy to middle life	Middle life to old age.
Onset:	Acute to insidious	Subacute to ignorance of presence.
Joint manifestations:	Periarticular and articular swelling. Often free fluid. Early limitation of motion considerable. In hands mid-phalangeal and metacarpophalangeal joints usually involved first	No periarticular and usually only localized articular swelling. Rarely free fluid. Little limitation of motion till late. In hands terminal joints usually involved first.
Symptoms:	General health usually less robust. Ptotic type. Pain and disability usually more marked	General health usually robust. Well nourished type. Pain and disability usually less marked.
Early radiogram:	No discoverable cartilage or bone changes. Shadows of excess of fluid and general increased density of soft parts	Early slight "lipping" of articular margins. Shadows of localized synovial membrane proliferations may or may not be seen.
Late radiogram:	Diminished density of bones. Usually absence of hyperostosis. Narrowed articular cartilage space. Ends of bones fairly regular in outline. Bony ankylosis common	Except after long disuse no diminished density of bones. Presence of marked hyperostosis. "Joint mice." Narrowed articular cartilage space. Ends of bones irregular in outline. Bony ankylosis rare.
Temperature:	In early stage often slightly elevated. In late stage often subnormal	Normal.
Blood pressure:	Usually lower than normal for age	May be low, but usually normal or high for age.
Morbid histology:	Early proliferation of synovial membrane. Pannus. Usually small round-cell infiltration. Late atrophic and destructive changes in cartilage and bone. No cyst-like cavities in ends of bones. Fibrous or bony ankylosis common	Early fibrillation of cartilage. Chondro-ossous hypertrophy Cyst-like cavities in ends of bone. Bony ankylosis rare.

arthritis. Gonococci have been found in these joints.¹⁹ The disease has been arrested and in early cases cured by the eradication of the deep foci of the primary infection.²⁰ We have all known similar recoveries to have quickly followed the removal of other foci of infection in the tonsils, teeth,²¹ sinuses, and intestinal canal, but it would seem that on the present evidence we have no conclusive proof that any known specific organism which invades and continues to inhabit the joints themselves can be held solely responsible for the disease.

We are beginning to accumulate suggestive evidence of the important part which faulty alimentation may play in the production of chronic arthritis. Woodward and Wallis²² and Baldwin²³ have shown a low hydrochloric acid in the gastric juice in cases of rheumatoid arthritis; and Clark²⁴ has found a very close association of gastro-intestinal derangements with the same disease. Pemberton²⁵ has made a series of close observations which show that in general these patients have a lowered sugar tolerance and a sort of carbohydrate intolerance. They do best on diets in which the carbohydrate calories are cut down to the lowest level which can be maintained without loss of weight. Fletcher²⁶ has recently confirmed these observations on 150 unselected cases. Nichols and Richardson, approaching the disease by a careful investigation of the morbid histology of material obtained from 65 early and late cases of chronic arthritis, came to the conclusion that the changes which they observed in the rheumatoid type might result from a great variety of irritants, such as infections, disease, and trauma. They suggest that the primary changes once produced may act in a vicious circle, with or without the primary cause continuing to be active.

Since careful and seemingly thorough experimental and laboratory study of the disease has not been thus far completely illuminating, it may be well to turn to the clinical aspects of the condition in a search for etiologic light.

My own clinical observations lead me to believe with Garrod²⁸ that everything which causes debility or loss of tone to the articulation acts as a predisposing cause, and with Pemberton that probably a variety of factors influence the substratum—for example, various types of infections, exposure to wet and cold, intestinal disturbances, endocrine imbalance. Pemberton²⁹ also believes that the changes found are associated with a low blood supply and disturbances of capillary control.

One other clinical observation to which Goldthwait³² has directed attention, and which has impressed me greatly, has been the common incidence of the disease in the so-called congenital viscerotonic type of individual—Treves's³³ and Bryant's³⁴ carnivorous type and Bean's³⁵ hyperontomorph. The female sex is more susceptible to ptosis and to the disease than the male, but in both sexes the type runs surprisingly true. Poor body mechanics,

vasomotor changes, faulty alimentation, endocrine disturbances, general lack of resistance to infection, and lowering of the vitality, perhaps worry and mental strain—these seem to be the predisposing clinical factors; and the joint changes once initiated may continue to progress until by some means—removal of serious focal infections, restoration of endocrine balance, relief of imperfect alimentation, correction of bad body mechanics—this general resistance can be raised, the lowered blood supply to the joints and the disturbance of capillary control overcome, and the complicated parts of the body machine coaxed again to function in harmony.

We have been unable positively to identify Still's disease as a separate entity. The disease in children seems to present certain peculiarities—for example, frequently a more general glandular enlargement and a more profound constitutional disturbance. No specific etiology has been worked out, and faulty alimentation is often, we believe, the most favourable point of attack.

Therapeutic Indications.

I do not feel that the general experience of clinical observers with vaccines and non-specific protein therapy has, by and large, been as hopeful in respect to permanent cure as the earlier reports suggested. My own limited trial of these methods is in accord with this general experience. The recent interesting articles of Professor Stockman³⁶ and Dr. Campbell³⁷ of Glasgow seem more encouraging.

I do not feel that the surgical removal of possible foci of infection, with some reservation as to those of the intestinal canal, has been followed in the majority of cases by the amelioration of symptoms which the patient had been led to expect; surely not in the well advanced type of case which usually in our country consults the orthopaedic surgeon. Let me not be misunderstood. It is of indubitable importance to eradicate, surgically or medically, any focus of infection which may reasonably be held responsible for any lowering of the general resistance, just as it is of greatest importance to adjust any discoverable endocrine disturbance or correct the faults of body mechanics. I suggest, however, that the reason for these procedures be made clear to the patient, and that, remembering our clinical experience, we stay the surgical and dental hands of our confreres, unless they can assure us that the foci of infection are affecting the general health of the patient and are not simply themselves expressions of a lowered vitality for which there are other causes. If we expect joint recovery to follow the removal of even well demonstrated possible foci, in a large proportion of the cases we shall find "Hope such a poor virtue that Disappointment pays her debts."

There is much to suggest that the path is very open

by which bacterial or chemical toxins may pass from the intestines, especially the colon, to the joints, and I urge most careful attention to normal evacuation of the bowels by means of mechanical correction of ptosis, abdominal massage, colonic irrigation, and non-irritating catharsis by mouth. A daily movement of the bowels, naturally or artificially produced, does not necessarily mean a safe and complete evacuation. The rather rare case, usually of short duration and fairly acute onset, which recovers spectacularly after the removal of a frank surgical focus, is quickly reported and too often considered the type. The case which begins to improve when it is possible to bring about a more normal rate of passage of intestinal contents and to secure a more complete evacuation of the colon, is perhaps less spectacular, but we believe much more common.

Of drugs I have little to say. Aspirin and salicylates surely relieve pain, and in small doses are useful for this purpose, but my impression is that in large or prolonged doses they are harmful to the digestive processes, and at no stage of the disease do they seem to exert a beneficial effect on its course. In a surprisingly large number of these cases the readings of the basal metabolism tests have been found well below normal, and their toleration of thyroid extract given in carefully graded doses to be considerable.

There is much evidence to suggest that the immediate cause of the crippling joint changes is directly due to a lowered blood supply and loss of capillary control, so that physiotherapy in the forms of heliotherapy, active motion to toleration, non-irritating massage general and local, diaphoresis by means of low temperature steam baths, radiant light, and perhaps diathermy locally—a fresh air and heliotherapeutic regime—is surely indicated. Occupational therapy has a great place in the treatment of these cases, and special exercises, often taken in recumbency, not so much of the standardized Swedish type as those designed to increase the vital capacity and relieve the ptosis, are with us prescribed as a routine. I should be unfaithful to our cult if I did not stress the great importance of the prevention of deformity. Here our orthopaedic skill will be taxed to devise apparatus, walking splints, weight and pulley traction, etc., to make sure that contractions do not occur and that the greatest amount of motion shall be conserved. I would warn against prolonged fixation or splinting in this type, because it still further lowers the already low blood supply and increases the atrophy. Even a surgical giant cannot scale Olympus by “piling Pelion on Ossa.”

Surgery in Rheumatoid Arthritis.

Have we a rational surgical attack on these joints themselves? Surely not in the acute stage, unless occasionally to relieve the hypertension of a joint by aspiration; perhaps not until the disease seems well under control. Then we are inclined to believe that the local progressive intra-articular changes, especially in the cartilage, may be checked and function conserved by the operation which has been called synovectomy. Goldthwait first advocated and practised the removal of joint fringes and pannus. The operation as it is understood to-day was introduced, we believe, by Mr. A. H. Tubby⁶⁰ in 1908, who removed all the proliferated synovial membrane and pannus from three knee-joints, with relief of local symptoms and the conservation of motion. Lately Swett⁶¹ and Jones⁶² have reported larger series of encouraging results.

Is it not probably conservative surgery, when we believe the process arrested, to remove these painful villi and the mass of pannus which eventually causes destruction of the articular cartilages, before this irreparable damage has been done? If deformities have occurred and complete or nearly complete ankylosis has taken place, resection will often bring about better weight-bearing lines by depriving the joint of all motion and will establish painless function. Manipulations of the quiescent joints after the carefully outlined methods of Sir Robert Jones⁶³ are often of great value in correcting malposition and even restoring motion. No successes have followed our attempts at arthroplasty on the knee-joints of these wasted limbs. Two stiff hips with limited or absent knee-joint motion represent an

enormous handicap, and while in these old cases perfect arthroplasties are as rarely accomplished in the hip as in the knee, some form of pseudarthrosis like that of Sir Robert Jones,⁶⁴ the reconstruction operation of Whitman,⁶⁵ or even a simple excision, allows the patients limited locomotion, with or without crutches, and makes it possible for them to sit in a chair with comfort. It is a fearful hardship to be obliged to be continually either completely *upright* or completely *downright*. To be able to receive attention without attracting it is a great blessing.

SPONDYLITIS DEFORMANS.

Rheumatoid Arthritic Type.

In discussing spondylitis deformans we have placed under the caption of rheumatoid arthritis that form described as the Strümpell-Marie type, the so-called spondylose rhizomélisque, or “poker back.” There is little chondro-osseous proliferation, but a gradual ossification of the spinal ligaments and intervertebral capsules, resulting in a complete bony stiffening of the spine and an ankylosis of the costo-vertebral articulations. There is also frequently a fusion of the root joints, the shoulders, and the hips. Our present knowledge would lead us to discuss its etiology as we have discussed the etiology of the general type of rheumatoid arthritis, recognizing the fact that this crippling spinal affection has frequently been observed to follow an infection of the prostate gland.

The orthopaedic aspects are of great importance. The early signs of this vertebral affection are definite—limited motion of the column and diminished chest expansion. We should never fail to recognize these early signs. The progress of the disease is often difficult to check, but the prevention of deformity is not difficult. If the intervertebral and costo-vertebral articulations are to ankylose, we must see to it that they ankylose in such a position that the action of the thoracic viscera, the lungs, and heart, and diaphragm shall suffer the minimal interference with their function. Again, attention to body mechanics should be our first concern. It is often possible, even after marked degrees of stiffening have occurred, to increase greatly the capacity of the thoracic cage by means of enforced positions, exercises, braces, and corrective jackets. Long and by no means intolerable life is possible with a completely rigid spine if the lungs and heart are allowed space in which to function and the diaphragm in which to act.

OSTEO-ARTHRITIS.

Etiology.

The type of chronic non-tuberculous arthritis which is generally designated in Great Britain as osteo-arthritis, and is more often spoken of in America as hypertrophic arthritis, demands less review as to its etiology than the rheumatoid type, for, unfortunately, it has been the subject of less thorough investigation. Climatic conditions offer little clue to its causation. As in rheumatoid arthritis, Strangeways has found that the tropics and the polar regions seem to furnish few examples of the disease. Exposure to cold and wet is a less frequent history than in the first type. Lowered general vitality is rarely demonstrable before the onset. Definite trauma is often prominent in the patient's mind, and repeated unnoticed traumata and the malalignments of joint surfaces, the “incongruence” of Preiser,⁶⁶ can often be found for the searching. Intra-articular fractures are usually followed by such changes.

Except for the rather rare frankly traumatic case the age incidence is striking. It is a disease of middle or late life, and is no respecter of persons or sexes or social standing. The early joint changes which are obvious to physical examination and Roentgenologic study are slight or moderate localized joint swellings, ridging of the articular ends, and chondro-osseous overgrowths at the margins of the cartilage. Eventually if the process is unchecked the articular cartilage disappears, leaving an eburnated bone end often irregular in contour, interlocking but not uniting with its opposing joint element. They are called “Heberden's nodes” in the fingers, “malum coxae senilis” in the hip, and “ring bone” in the spine. Nichols and Richardson⁶⁷ found the earliest changes to

consist of a fibrillation of the cartilage. Clinically the joint disturbances under discussion do not often suggest any inflammatory process, certainly not as much as the disturbances in gouty joints, for which we hold responsible, not an infection, but faulty body chemistry.

There is some evidence to support the etiologic theory of faulty body chemistry. Haygarth,⁶⁹ and recently Cecil and Benjamin,⁷⁰ have called attention to the fact that many cases of this type appear at about the time of the menopause in women, and Cecil has observed this to be true in certain patients in whom an artificial menopause had been induced. Cecil could establish no relation to possible alveolar foci, many of his patients having had all their teeth extracted years before the onset of the trouble. My experience has not been that of Mr. Fisher, that the removal of surgical foci has favourably influenced the condition of the joints, unless these foci were profoundly affecting the general health of the patient. Ely^{67(c)} holds an amoeba probably responsible.

Rheumatoid arthritis usually appears in the light, ptotic, carnivorous type—the hyperontomorph of Bean. Osteoarthritis usually appears in the heavy, herbivorous type—the hypo-ontomorph of Bean. As the patients usually present themselves, they describe their general health as excellent and their appearance does not belie their words. They have been active men and women, their digestions have been excellent, their bowels usually fairly regular, their weight is often above normal, but one or more of their joints are beginning to “bother” them and to interfere with activities for the pursuit of which they still feel a zest.

Therapy.

The orthopaedic aspects of this type of chronic arthritis are more striking and of even earlier concern than in the rheumatoid type. They may be said to present themselves at the very earliest sign of the onset of the process. The local therapeutic indications are to maintain and stimulate the blood supply of the joint by heat and massage about, but not on, the chondro-osseous ridges, and by intermittent active, painless motion, but not by manipulation. First and foremost, we must diminish in every way intra-articular friction.

These joints do not ankylose except in the spine and pelvic joints, where one chondro-osseous spicule directly impinges upon, and finally fuses with, another. We need not fear that fibrous or bony fusion will result from even complete immobilization. The spicules and ridges of bone at the articular margins which the Roentgen ray reveals are capped by a sensitive cartilage which proliferates from the irritation of frictional motion. Protect the sensitive ridge, limit joint motion, or even temporarily completely deprive the joint of motion, and the irritation will subside. The roentgenogram later will show no change, but the patient will often declare himself completely relieved. If he is willing to restrict his activities to the limit of non-irritating use, his joint function may represent the least of the incapacities of his increasing age.

This rest and protection of the affected joints, with painful active or passive motion always discouraged, we believe to be our first therapeutic indication, although it is a purely local one. The next indication is a more general one, and has to do with body mechanics. We should strive to bring about as perfect an alignment of the weight-bearing mechanism as it is possible to attain. This may mean the relief of knee strain by the correction of pronated feet, the relief of low back and hip strain by the adequate support of a pendulous abdomen, the neutralization of dorsal and shoulder girdle and cervical strain by suitable braces. Do not understand me as advocating these initial measures as of more importance than an attempt to discover the underlying biochemical cause of the joint changes. This is, of course, our ultimate goal, but our initial endeavour should be at the earliest moment to prevent, by local measures, processes which to many of us seem essentially degenerative from being accentuated by “wear and tear.” In general the patients do better on a low protein and fat intake, a low meat and sweet, and low acid-forming diet, as do the gouty cases. The endocrine disturbances have not been so common in this type.

Surgery in Osteo-arthritis.

Surgery may offer temporary and sometimes permanent relief in difficult cases. We often hear manipulation of these joints advocated. This is justifiable in those rare cases in which contractures have taken place or malpositions of weight-bearing have occurred and in those monarticular cases in which repeated attacks have left adhesions. Intra-articular adhesions are uncommon in the polyarticular case, and in my experience forcible manipulations, save to secure better functional positions, have rarely afforded more than temporary relief, and have seemed to affect unfavourably the course of the local process. Unless prolonged fixation follow the manipulation, the old faulty position is soon reassumed. I am aware that my experience has not been that reported by other clinicians, but it is definite none the less.

Loose bodies arising from detached chondro-osteophytes or synovial membrane fringes are often greatly incapacitating, as they are especially prone to occur in the knee-joint, and these with fringes which catch between the articular ends, and chondro-osteophytes which impinge, often make arthrotomies justifiable. Their removal may afford a long relief, without, of course, the assurance of their non-recurrence. These operations should be performed only after the disease has been rendered quiescent by a period of adequate protection. The underlying pathologic process militates against the success of nice arthroplastic operations, and because of the eburnation and cyst formation in the ends of the bones, makes it difficult to obtain firm bony union after resection. Fortunately, the operation of arthrodesis is rarely indicated in any of the joints affected by the disease, the hip-joint alone excepted.

Malum coxae senilis presents a special problem. Local protection of the other joints usually makes life tolerable, and even in the hip, if the functional position be not too bad and the patient is willing to suffer the inconvenience of a stiff spica, or even some less radical protective appliance, pain and discomfort may be relieved.

Dr. Royal Whitman⁷⁶ has recently applied with success his reconstruction operation to cases of arthritis deformans of the hip-joint. I have followed several cases in older subjects whose deformed femoral heads have been quickly resected with no attempt made to reconstruct a stable joint. Convalescence has been rapid and pain relieved. Though I cannot speak from personal experience, I believe one of the most useful and least shocking operations in “elderly and fragile patients” is the pseudarthrosis of Sir Robert Jones. In these older cases surgery is surely the last resort, seldom demanded and always hazardous. In some of the extreme cases in good surgical risks an attempt at an arthrodesis seems to be the method of choice. If this choice is taken the operation in a well advanced case demands a complete exposure and disarticulation. Only the most thorough procedure offers a reasonable chance of success.

SPONDYLITIS DEFORMANS.

Osteo-arthritic Type.

Under the caption of osteo-arthritis we have placed those forms of spinal affections described by von Bechterew, the hereditary traumatic kyphosis, and the hypertrophic arthritis of Goldthwait. It differs in no way either etiologically or pathologically, in our opinion, from the other articular manifestations of osteo-arthritis, except that the chondro-osseous ridges and spicules at the margins of the vertebral bodies are prone to impinge upon one another and occasionally eventually unite. In subjects who bear heavy burdens on their shoulders or assume an habitual posture of stoop shoulder, a rounded, rigid dorsal kyphosis ensues. Though the intervertebral foramina themselves are usually free from osseous changes, the chondro-osseous ridges may impinge on the nerves after their exit from the intervertebral foramina. Brachial, intercostal, and sciatic pain are, therefore, not uncommon symptoms of this disease when it affects the spine, and a localized or general rigidity of the back is nearly always present. The roentgenograms of spines taken for suspected kidney or other visceral lesions frequently reveal well marked osteo-arthritic changes often when the subjective symptoms of this type of articular change are entirely absent.

The orthopaedic aspects of the condition concern us very acutely, especially since industrial insurance and workmen's compensation cases have become so numerous. The therapeutic indications are the same as in other types of the condition: attention to general health and free elimination, physiotherapy, protection of the affected portion of the spine by a Thomas collar, a spinal brace or jacket, and an attempt to neutralize or correct the faulty spinal curves and bring about a normal weight-bearing alignment. Conceivably a spinal fusion operation might be a rational procedure in an occasional case. Relief from less radical measures is ordinarily easy to obtain, and for this, in the commonly met cases exhibiting low back pain and sciatica, the low short back brace with an abdominal supporting pad devised by Goldthwait has been a sheet anchor which has held. If rest of the affected part, diminution of intra-articular friction, and free elimination can be provided, we may expect symptomatic relief.

SUMMARY.

1. Rheumatoid arthritis is a disease in which no specific organism has been found which can be held constantly responsible for its causation. Probably many different types of organisms and many other factors play etiologic parts in its onset and course.

2. In the early stages of rheumatoid arthritis, if these organisms and if the other factors can be overcome, complete recovery is possible. In the later stages, if the factors inimical to normal vitality can be eliminated and the essentials for normal body mechanics can be satisfied, arrest of the disease and great functional betterment may be expected. In this stage the simple eradication of a possible surgical focus of infection will rarely be successful in controlling the progress of the disease.

3. Osteo-arthritis is a disease in which no specific organism has been conclusively proved to be responsible for its causation. On the basis of the present evidence, its manifestations may occur unassociated with any demonstrable remote or local focus of infection.

4. In the early stages of osteo-arthritis, if a faulty body chemistry and a faulty body mechanics can be corrected and intra-articular friction can be lessened, almost complete relief of the subjective symptoms is possible. In the later stages, if intelligent physiotherapy, protective appliances, and well conceived surgery be added to these measures, relief of discomfort and greatly improved function may be expected.

PHRENIC EVULSION AS AN AID IN THE TREATMENT OF PULMONARY TUBERCULOSIS AND BRONCHIECTASIS.

BY

H. MORRISTON DAVIES, M.A., M.D.,
M.CH.CANTAB., F.R.C.S.ENG.,MEDICAL SUPERINTENDENT, VALE OF CLWYD SANATORIUM; CONSULTING
SURGEON, UNIVERSITY COLLEGE HOSPITAL, AND KING EDWARD VII
WELSH NATIONAL MEMORIAL ASSOCIATION, ETC.

(With Special Plate.)

Is pulmonary tuberculosis it is quite common to find by radiological examination a reduction of the range of movement, or a delay, or, occasionally, complete immobility of one or both domes of the diaphragm. This reduction in the mobility of the diaphragm is not of the nature of a paresis or paralysis, but rather of a tonic contraction, exercising probably the same type of protective function as is seen in the rigidity of the muscles of the back in cases of pulmonary tuberculosis, or of the abdominal muscles in intra-abdominal lesions. The rigid diaphragm will, in chronic fibrotic cases, become drawn up somewhat into the thorax and so aid slightly in reducing its volume. In the upward displacement, if the base of the lung is adherent to the muscle, distortion will be added to the upward displacement. This tonic spasm becomes an added factor in disturbing the normal reflexes of respiration, and is therefore a contributory agent in the production of dyspnoea. Briscoe has stated that when the phrenic nerve is involved by pressure due to neoplasms, etc., dyspnoea is at first one of the striking features of the clinical picture; later, when doubtless the irritation of the pressure has given way to paralysis, the dyspnoea subsides.

When the phrenic nerve is paralysed by severance of the nerve supply the condition, as seen by radiological exami-

ination, is very different. There is complete loss of tone of the muscle, and the dome (when one half is paralysed) occupies a higher position in the thorax. On the right side the elevation may be from 4 to 8 cm.; on the left side it is less—from 2 to 4 cm. The maximum rise is not seen at once; the initial change in position is increased during the ensuing weeks as the muscle atrophies. The rise is due partly to the pull of the intrathoracic negative pressure, but mainly to the upward pushing force exercised from the abdomen by the abdominal muscles. During ordinary respiratory movements the paralysed dome is immobile. In most cases, but not in all, paradoxical movements can be observed during deep respirations—that is, the paralysed dome will rise still further into the thorax during inspiration and will sink back during expiration. These movements, according to Landé, are especially noticeable with Bittorf's method (that is, inspiration with closed nose and mouth).

The effect of the paralysis is twofold: it prevents the diaphragm pulling on the lung and expanding the lower lobe; it also does what is of such value in the treatment of certain types of disease—it produces a partial collapse of the base of the lung. Such collapse varies considerably in different cases, depending probably on the absence or the extent of the adhesions in the *costo-phrenic sulcus*. As there is rest of the lung and collapse of the base, benefit is derived from the diminution in the outpouring of toxins into the lymph stream. The realization of these facts aids the appreciation of the value of unilateral diaphragmatic paralysis in the treatment of certain pulmonary diseases, especially when localized at the base.

So much disappointment was experienced by the repeated failure of simple phrenicotomy that the operation fell into comparative disuse. Willy Felix published in 1922 a paper giving the results of his anatomical, experimental, and clinical researches on the phrenic nerve and the innervation of the diaphragm. His work explained the previous failures, which, until then, had been somewhat vaguely attributed to the existence of additional nerve fibres to the diaphragm said to run with the nerve to the subclavius.

Briefly, Felix's findings are as follows. The main nerve supply to the diaphragm is the phrenic nerve; the last intercostal nerve does send some filaments to the muscle, but these are of no consequence. The important point is that the phrenic nerve when it reaches the diaphragm does not always consist only of the fibres of the phrenic nerve as found in the neck. It may receive fibres from the nerve to the subclavius muscle; it may also receive them from the hypoglossal, the spinal accessory, the vagus, or the suprascapular nerves, either directly or through the *ansa hypoglossi*. But of much greater importance is the fact that the phrenic nerve is often duplicated in the neck. In such cases, the true phrenic occupies the usual course, traversing the *scalenus anticus* muscle from without inwards and entering the thorax *behind* the subclavian vein. The accessory phrenic, when present, lies at first some 3 cm. lateral to the true phrenic. It originates from the fifth cervical and frequently runs in close contact with the nerve to the subclavius muscle, leaving it just before that nerve enters the muscle. The accessory phrenic then enters the thorax *in front* of the subclavian vein, crossing the *scalenus anticus* at its point of insertion into the first rib. Either at this spot, on the inner side of the muscle, or behind the innominate vein, or even at some lower

point in the thorax, the accessory joins up with the true phrenic. This double phrenic occurs in at least 20 or 25 per cent. of people, according to Felix. Goetze, who has also examined a series of bodies, found that in 68 per cent. of them there were accessory branches to the main nerve. In one case the accessory phrenic joined the true phrenic at a point 3 cm. only above the diaphragm. Ruheman, in his examination of 17 bodies, found some abnormality—that is, a condition other than that of a single phrenic nerve—in 11 of them. In 4 there was a bilateral accessory phrenic; in 3 the accessory phrenic ran with the nerve to the subclavius.

It is only necessary to appreciate how frequently the main phrenic nerve is supplemented by fibres reaching it during some part of its course (usually in the thorax) to understand why the old operation of phrenicotomy—that is, simple section of the nerve in the neck—is almost more likely to fail in producing the required result than it is to succeed.

Two operations have been devised to ensure complete

FIG. 1.—Diagram illustrating the phrenic nerve occupying a normal position in relation to the *scalenus anticus* muscle, and entering the thorax deep to the subclavian vein. The commonest variety of the accessory phrenic is also shown. It arises from the upper trunk of the brachial plexus, which it crosses superficially, to reach and enter the thorax, passing superficial to the subclavian vein. The intrathoracic junction of the phrenic and accessory phrenic nerves is shown by dotted lines.

paralysis of one dome of the diaphragm. (1) The radical operation of Goetze. Goetze makes a long incision along the posterior border of the sternomastoid muscle. Through the lower end of this he exposes the phrenic nerve and divides it as low as possible, so as to cut off the sympathetic fibres from the inferior cervical ganglion. Then, through the upper part of the incision, he exposes the fifth cervical root, identifies the nerve to the subclavius muscle, and divides this. This operation has not found favour. (2) Phrenic evulsion (phrenic exaeresis) suggested by Thiersch, and first done by Willy Felix; the phrenic nerve is divided in the neck and the peripheral end is twisted and pulled out of the thorax. When complete evulsion is obtained the various terminal branches are plucked out of the diaphragm; frequently, however, the nerve breaks at some point in its intrathoracic course.

The theoretical objections to phrenic evulsion are:

1. The phrenic nerve may rupture at a point above that at which the main stem is joined by the accessory.
 2. Bleeding may occur from the pericardio-phrenic artery, which accompanies the nerve in its intrathoracic course. In one case Sauerbruch had to open the chest after evulsion and evacuate 2 litres of blood.
 3. The phrenic nerve entering the thorax behind the subclavian vein, while the accessory enters in front of it, means that when the former nerve bundle has strong traction exerted on it the vein is caught in the loop and dragged on. Theoretically the vein might rupture before the nerve bundles give way. This has never occurred.
 4. Changes in the pleura, in the neighbourhood of the nerve have led to the implication and inclusion of the nerve, which becomes embedded in the organized lymph deposit. Traction on the nerve trunk may lead to rupture of it proximal to its point of fixation; on the other hand, the thickened pleura round the nerve may get torn away and expose the mediastinum to infection from pus, if such is present in the pleural cavity. Similarly, the nerve may have become attached to the surface of the lung or to a gland, and rupture of either of these may occur, with resulting pneumothorax or pyo-pneumothorax.
- Experience, which now includes many hundreds of cases, shows that these dangers are more hypothetical than real. One other danger must be mentioned, but chiefly as a warning: on four occasions the vagus nerve has been mistaken for the phrenic, with fatal results each time.

The bleeding from cut veins may be merely "troublesome," but there is also the danger of air embolism, which has occurred on more than one occasion. Zadek has on two occasions seen haemoptysis during the operation; he and Felix have both seen temporary cardiac failure. Reflex cardiac and respiratory phenomena have been reported by H. Alexander. J. Alexander says: "Dyspnoea, rapid or slow, weak and irregular pulse are usual during the actual twisting of the nerve." Morone has seen one case of dyspnoea following the operation. This hitherto has not been my experience, except in so far that during traction when the nerve parts company with the diaphragm the sudden rebound which occurs at that moment usually causes a momentary gasp and an acceleration of the pulse rate. I have observed the pulse weaken and a feeling of faintness come over the patient temporarily on three or four occasions, but there has been nothing to indicate that this is a direct reflex due to traction on the nerve as opposed to the mental strain associated with any operation done under a local anaesthetic.

INDICATIONS FOR PHRENIC EVULSION.

1. As a means of arresting disease in cases of basal tuberculosis and bronchiectasis. It must be understood that, wide as is the range over which unilateral paralysis of the diaphragm can be regarded as efficacious, its value is chiefly as an accessory to other forms of treatment, as a means of controlling symptoms, or as an intermediate measure to enable other lines of treatment to be more complete or more successful or to be adopted after an interval of time. Only when the disease is strictly limited to the lower lobes can complete arrest be expected by phrenic evulsion as the sole method of treatment. The case of bronchiectasis given in detail later on (Case 1) is an illustration of the very successful results which can be hoped for, especially on the right side. Rist also quotes a case of bronchiectasis healed by phrenic evulsion.

2. Phrenic evulsion in association with local thoracoplasty is applicable to such cases as those described above but in which the disease is somewhat more extensive.

3. To assist in controlling the disease in more generally extensive or more advanced or more acute cases of pulmonary tuberculosis. Fischer, discussing radical phrenicotomy, says that the infiltrating, rapidly progressive, disintegrating forms of pulmonary tuberculosis, which so often give bad results with thoracoplasty, are exactly the type of case which give favourable results with phrenicotomy. Baemeister, with an experience of 38 cases, states that even those of the acute exudative type, which have resisted treatment, have been improved. Goetze states that phrenicotomy constitutes, with pneumothorax and thoracoplasty, a third useful operative method of treatment for pulmonary tuberculosis, and resembles pneumothorax in its freedom from danger. It has the advantage over pneumothorax in that it is a single operation with progressive efficiency. Sultau is in agreement with Sauerbruch rather than with Goetze; he considers that phrenic evulsion as the sole method of treatment should be used in exceptional cases only. J. Alexander states that phrenic evulsion has produced some startling results in acute, highly febrile, progressive, predominantly caseous types of the disease.

In the advanced type of case an amelioration only of the symptoms should be expected. In severe unilateral cases phrenic evulsion may be done when pneumothorax has failed, in the hope that sufficient improvement will occur to admit a thoracoplasty being done at some later time. In bilateral cases hemidiaphragmatic paralysis may be produced on the more affected side so as to obtain for the patient some diminution of the cough and sputum and some reduction of temperature. Landgraf has done phrenic evulsion on the more affected side in 20 cases with bilateral disease. Of these 4 were uninfluenced and 16 improved (in 3 there was disappearance of pyrexia and in 5 of sputum).

4. As an accessory to artificial pneumothorax treatment. Sauerbruch, Brunner, Zadek, Goetze, Sultau, Baer, Ziegler, and Schulte-Tigges are all greatly in favour of the combination of phrenic evulsion with artificial pneumothorax. When adhesions are present between the base of the lung

and the diaphragm, and are interfering with the pneumothorax, and are responsible for definite symptoms such as cough, etc., considerable improvement and relief may result from paralysing the dome. There is a general consensus of opinions that effusions are less frequent if the diaphragm has been paralysed, and that there is less rapid absorption of the gas, with the result that the intervals between the refills can be lengthened. Zadek estimates that the interval can be lengthened by 25 to 33 per cent. According to Sauerbruch, the interval can be doubled or even trebled. It is suggested that the diminution of movement is responsible for both these benefits; possibly also the removal of the drag on adhesions, when such are present, is also beneficial. Lastly, in conjunction with artificial pneumothorax, it is of great advantage to paralyse the dome of the diaphragm before permitting a lung, long collapsed, to re-expand. As J. Alexander says:

"To release an artificial pneumothorax and permit a scarred, shrunken lung to re-expand in an attempt to meet the chest wall is a hazardous procedure, and not rarely followed by emphysema, mediastinal displacement, dyspnoea, pain, unfolding of cavities, lighting up of infirmly encapsuled foci, and reactivation of the tuberculous disease. The narrowing of the chest, caused by the mounting of the diaphragm, largely compensates for the disproportion in volume between the unchanged capacity of the hemithorax and the diminished volume of the shrunken, fibrotic lung."

So valuable and helpful has the combination been found to be that it has been recommended as a routine procedure. Zadek does the phrenic evulsion before starting the pneumothorax; Goetze after.

5. Phrenic evulsion for the treatment of symptoms. Sauerbruch considers diaphragmatic paralysis of special value in that it makes coughing easier; this leads to freer expectoration and prevents stagnation of secretions. The beneficial effects are in turn seen in the reduction of pyrexia and the improvement in the general condition. In my experience this is undoubtedly the case. The value of hemidiaphragmatic paralysis in easing the cough needs even greater emphasis than is given to it by Sauerbruch, Brunner, and others. When the base of the lung is adherent to the diaphragm there is set up at times an intolerable irritating cough, which is dry and incessant. The slightest movement, even talking and laughing, may start it, and it is some minutes before it subsides. I have done phrenicotomy for the relief of this condition since 1914. Whenever the diaphragm was paralysed and raised into the thorax by the section of the nerve, the result was always most gratifying; now, with the substitution of evulsion for section, the much greater certainty of success makes one unhesitatingly advocate this method of easing a very distressing symptom. In three of the cases detailed later this reiterating cough was one of the main reasons for recommending phrenic evulsion. It is not only this type of cough which is benefited; the act of coughing, in general, is aided by the paralysis of the diaphragm. Cases have been recorded of the cessation of haemoptysis after phrenic evulsion (Morelli). It is more likely to be successful when the bleeding comes from the lower lobe. In such cases phrenic evulsion should undoubtedly be done if artificial pneumothorax is impossible or incomplete. The pumping action of the diaphragm on the stomach frequently leads to the association of vomiting with the morning bout of coughing, especially if this comes on during or immediately after breakfast. The same may occur after other meals. In two of the cases of my series this vomiting was one of the symptoms indicating the operation (see Cases 5 and 8). Sauerbruch has treated hiccup by bilateral diaphragmatic paralysis. The results have been successful, and have not been accompanied by any ill effects. It is astonishing what complete freedom from all unpleasant sensations there is after one dome of the diaphragm has been paralysed. Most patients are quite unconscious of any change in the region of the muscle, except one of relief. When there has been constant coughing, complaint may be made of intense soreness, aching, and even pain round the costal margin; these sensations will disappear completely after the muscle is paralysed. Two patients noticed a "hollow feeling" below the costal margin after the

operation. Usually there is a diminution of cough and sputum (there may be increase for the first day or two); a feeling of greater ease and freedom in breathing; dyspnoea is lessened; with it all there is the feeling of greater well-being.

6. *As a preliminary to thoracoplasty:* (a) As a test of the ability of the sounder lung to stand up to the increased work which will be imposed on it by the major operation; (b) as an aid in improving the general condition of the patient; (c) to prevent the development of catarrhal signs in the lower lobe.

7. *As a preliminary to radical treatment of a tuberculous empyema.* Sauerbruch and Brunner recommend that unilateral diaphragmatic paralysis should be produced before doing a thoracoplasty in cases of tuberculous empyema. The object is to reduce as far as possible the size of the pleural cavity so as to lessen the extensiveness of the subsequent operation.

8. *After imperfect resolution of pneumonia.* Pneumonia, when it subsides completely, leaves little, if any, trace; when resolution is imperfect fibrosis takes place and the volume of the lobe or lung shrinks. Following this, and as a natural consequence of it, bronchiectatic changes appear and progress. In from two to four years after the pneumonia the patient exhibits the complete picture of bronchiectasis. If the lung is allowed to contract freely during the early post-pneumonic fibrotic stage the bronchiectatic changes will not develop. Phrenic evulsion, by paralyzing the dome of the diaphragm and allowing it to rise into the thorax, will give to the affected lobe or lung the freedom to shrink in response to the contraction associated with the active changes of fibrosis.

9. *In order to free the heart from embarrassment.* In cases of extreme fibrosis of a lung there is very considerable displacement of the heart. This in itself may embarrass the heart's action. Such embarrassment is likely to be increased if there has been much pleuro-pericardial thickening. After phrenic evulsion the rise in the position of the diaphragm will allow some return of the heart towards its normal position and so tend to relieve the symptoms.

TECHNIQUE OF PHRENIC EVULSION.

The operation is done under local analgesia. Novocain 1 per cent. is used with adrenaline hydrochloride; 12 c.cm. should be sufficient completely to anaesthetize the field of operation. The patient is given also an injection of omnopon gr. 1/3, or morphine gr. 1/4.

The skin incision is either oblique along the lateral border of the sterno-mastoid muscle, 5 cm. long, the centre being 5 or 6 cm. above the clavicle; or transverse, 5 to 6 cm. above the clavicle, two-thirds being lateral and one-third mesial to the lateral border of the sterno-mastoid muscle. The skin, platysma, and fascia are divided and the lateral border of the sterno-mastoid is defined and exposed, and is then retracted mesially. The next landmark is the omo-hyoid muscle crossing the wound downwards and laterally. This is retracted downwards. The scalenus anticus muscle with the phrenic nerve crossing it is still concealed from view by fat, glands, and the deep cervical fascia. The dissection must be carried down through these and the muscle exposed. If the nerve is running a normal course it will now be seen crossing obliquely from above downwards and medially across the surface of the muscle. Care must be taken not to displace the nerve to one side with the fascia. During the deeper dissection the internal jugular vein will be seen on the medial aspect of the wound, and must be drawn to one side. The superficial cervical and suprascapular vessels can be seen running across the lower end of the wound.

It must be remembered that the course of the phrenic nerve is not constant; it may not come on to the anterior

surface of the scalenus anticus till low down in the neck; it may cross to the medial margin high up; at times it may run through the substance of the muscle. When the nerve is pinched with a pair of forceps the commonest sensation is one of pain referred to the shoulder or to the upper part of the arm. Sometimes a fluttering sensation is felt in the region of the costal margin, or a definite sharp contraction of the dome of the diaphragm can be both seen and felt.

The nerve is divided at the highest exposed point, and the cut peripheral end is seized in a pair of forceps. Traction is now applied, and as each successive length of nerve appears a Spencer Wells forceps is applied to it. This is to retain a hold on the nerve should it rupture immediately below the upper forceps through which the traction force is exerted. When some 10 cm. of the nerve has been slowly drawn out from the wound, an extra pull will probably rupture the filaments from the diaphragm and the whole nerve comes away. At the moment when the break occurs the patient usually experiences a sudden jerk at the base of the chest. The operation is now concluded by stitching together the divided deep fascia, the superficial fascia and platysma, and the skin.

If the whole of the peripheral part of the nerve has been evulsed, the part extracted will be found to consist of the trunk and the main terminal branches. The trunk of one nerve so evulsed was 30 cm. long, while the main branch was an additional 10 cm., making a total length of 40 cm. Another similarly complete evulsion from a small woman gave a total length of 24 cm. These have been the extremes in the cases recorded here.* It is generally held that if a total length of 11 to 12 cm. of the nerve has been evulsed this, in the great majority of cases, will have necessitated rupture of the accessory phrenic, if present.

In three of my cases I have abandoned the attempt at complete evulsion, because in each the same phenomenon was observed, and I decided that discretion was the wiser course. After the first 6 cm. or so of nerve had appeared, instead of the diaphragmatic pull one usually feels, I obtained arterial pulsation. The stronger the force used the greater became the pulsation. In these cases, therefore, I divided the nerve as low down as possible. In each case the diaphragm was found afterwards to be paralyzed on the side of the operation and to be raised up into the thorax; in two of the cases there were paradoxical movements. Most Continental surgeons exercise a torsion force as well as a traction force, giving the nerve not more than one complete turn a minute round its long axis.

Perret, Pignat, and Giraud, summarizing the results of phrenic evulsion, say:

"The results obtained in the most successful cases, as a result of phrenic exaeresis, can be likened to those of the other plastic operations, though they are rarely as complete. Between the successful and the unsuccessful there is room for the whole range of partial success characterized by the improvement of such and such a symptom, physical, functional, or general. . . . The inconstancy of the results must, in our opinion, be attributed to two principal causes: (1) incomplete evulsion of the phrenic and its anastomoses; and (2) cases wrongly selected."

I have now done phrenic evulsion twenty times.† The cases come under the aforementioned groups as follows:

1. For the purpose of arresting disease . . .	3
2. In conjunction with local thoracoplasty . . .	0
3. To assist in controlling disease . . .	4
4. As an accessory during artificial pneumothorax treatment . . .	5
5. For the treatment of symptoms . . .	2
6. As a preliminary to thoracoplasty . . .	4
7. As a preliminary to the radical treatment of a tuberculous empyema . . .	2
8. After imperfect resolution of pneumonia . . .	0
9. To free the heart from embarrassment . . .	0

* In a later series I have evulsed a nerve the trunk of which was 29 cm. long and the terminal ramifications 17 cm.—total 46 cm.

† I have since done phrenic evulsion an additional fourteen times.

FIG. 2.—Drawing of an evulsed phrenic nerve, showing the main trunk (not in its entirety) and the terminal ramifications.

FIG. 3.—Case 1, before operative treatment. The semicircular wire shadows mark the nipples. The shrapnel can be seen immediately above the right dome of the diaphragm.

FIG. 4.—Case 1, ten days after evulsion of the right phrenic nerve.

FIG. 5.—Case 2. Skiagram taken the day before phrenic evulsion. Partial pneumothorax on the left side.

FIG. 6.—Case 2. Skiagram taken seven days after evulsion of the right phrenic nerve.

FIG. 7.—Case 3. Skiagram taken eight days after evulsion of the right phrenic nerve.

FIG. 8.—Case 8. Skiagram taken about seven weeks after evulsion of the right phrenic nerve.

FIG. 9.—Case 8. Skiagram taken five months later to show the increase in the heightened position of the right dome of the diaphragm and the greater collapse of the right lung.

FIG. 10.—Case 14. Skiagram taken before phrenic evulsion.

FIG. 11.—Case 14. Skiagram taken six months after evulsion of the left phrenic nerve.

FIG. 1.—Ovarian pregnancy; antero-posterior view.

FIG. 2.—Ovarian pregnancy; postero-anterior view.

FIG. 3.—Ovarian pregnancy; side view.

FIG. 4.—Normal pregnancy; postero-anterior position.

The following is a synopsis of the cases. With the exception of Case 1 the operations were all done under local

Case 1 (Group 1).—E. M., aged 39. (V.C.S.) In 1918 gunshot wound right side of the neck. Division of the recurrent laryngeal nerve. Subsequent operation in the front of the neck, and dorsal vertebra. Drainage tube passed down posterior mediastinum and gradually became worse. Sputum at times extremely offensive. Admitted October, 1924. Incessant cough and the expectoration of some 4 ounces of offensive sputum per diem. Breath and bronchiectasis, chiefly of the right lower lobe. In December, 1924, the right phrenic nerve was evulsed. The operation was very difficult because of the great distension of all veins. The phrenic nerve was apparently caught in scar tissue, and traction on it caused considerable pain; a little chloroform was therefore given. The nerve ruptured and 11 cm. were evulsed. The irritating cough disappeared at once, while the sputum diminished rapidly and lost all offensive odour. Radiograms showed that the right dome of the diaphragm had been raised 7.5 cm. above its original position (this is the highest immediate rise I have seen), while the foreign body had been shifted 5.5 cm. Paradoxical movements were present on deep respirations; no movement of the right dome during shallow respiration. In April, apart from an occasional spit first thing in the morning, he was untroubled by cough, sputum, offensive odour, or dyspnoea. This patient was sent to me by Dr. E. A. Peters, London.

Case 2 (Group 1).—Mrs. Ch., aged 27. (V.C.S.) On admission left lung only involved. Artificial pneumothorax started September, 1921. Kept very well till November, 1925. In January, 1924, artificial pneumothorax was started on the right side also, that on the left being maintained, but to a less degree. Again, the patient responded well to treatment and became free from symptoms. In April, 1925, the patient was extremely well, but in May there was again a relapse due to extension of the disease to the uncollapsed lower lobe of the right lung. The artificial pneumothorax on the right side was abandoned. In June, 1925, the right phrenic nerve was evulsed, 11 cm. of nerve being extracted. The sputum was at first increased and then diminished. Screen examination showed that the right dome of the diaphragm was paralysed and raised into the thorax; there were no paradoxical movements. On August 30th, 1925, she was much improved; there was considerable lessening of cough, sputum, and dyspnoea. January, 1926: There are practically no symptoms.

Case 3 (Group 1).—Mrs. B., aged 31. (N.W.S.) Clinical and radiological evidence of tuberculous involvement of right lower lobe. On May 4th, 1925, right phrenic evulsion was performed, 10 cm. of the nerve being extracted. The nerve lay on the lateral side of the scalenus anticus muscle, which it crossed just above the insertion into the first rib. With it ran another nerve, the two being closely connected in the upper part of their course. This second nerve left the phrenic in the lower part of the neck and turned outwards across the posterior triangle. The appearance of these two nerves suggests that the normal phrenic was absent and that the whole of the nerve supply to the diaphragm was in the accessory phrenic which ran with the suprascapular nerve.† Seen six weeks after the operation, the diaphragm was found to be raised and immobile. There was no paradoxical movement. The cough and sputum had ceased except for a very occasional dry single cough and a spit once or twice in the week.

Case 4 (Group 3).—E. L., aged 23. (P.P.) A long history of very chronic pulmonary tuberculosis involving the left lung, but mainly the lower part. In June, 1925, the symptoms had increased; the cough was troublesome and there were 2 ounces of sputum per diem. He had pain and discomfort over the left base and was unable to lie on that side. On June 12th left phrenic evulsion was performed. In this case the nerve did not give way, but was cut after the first stage of the evulsion owing to the strong pulsation felt on continuing the traction; 8.5 cm. only were excised. A week later the cough and sputum were reduced to three or four coughs and spits in the twenty-four hours. The patient had lost the sensation of dragging at the base of the lung, was much more comfortable, and could lie on the left side. Screen examination showed that the left dome was raised and was immobile during quiet respiration, but that it became tilted during deep inspiration owing to the pull of the central tendon of the diaphragm.

Case 5 (Group 3).—Miss M. H., aged 23. (N.W.S.) Left lower lobe extensively diseased and very retracted; involvement of the left upper lobe also, but to a less degree. On July 15th, 1925, the left phrenic nerve was evulsed. The nerve was 21 cm. long. Screen examination showed that the left dome of the diaphragm was raised and that paradoxical movements were present. Left dome 2 cm. above right on shallow inspiration; 4 cm. above on deep inspiration. On August 31st the cough was still troublesome; sputum diminished in amount; temperature a degree lower.

* Explanations of abbreviations: V.C.S. denotes Vale of Clwyd Sanatorium, N.W.S. denotes North Wales Sanatorium, belonging to the Welsh National Memorial Association. These patients were under the care of Dr. Powell, medical superintendent, and Dr. Emrys Jones. P.P. denotes private patient under the care of Dr. Cropper, Ruthin.
† In a later series I have had two other cases with identically the same arrangement of the nerves.

Case 6 (Group 3).—M. W., aged 55. (V.C.S.) Extensive fibrotic and bronchiectatic changes in the right lung. On August 27th, 1925, the right phrenic nerve was evulsed. Total length 36.25 cm. (main trunk 25 cm.; terminal ramifications 11.25 cm.). Screen examination showed that the right dome had been raised 5 cm. There were slight paradoxical movements.

Case 7 (Group 3).—Miss V., aged 47. (V.C.S.) About 5 ounces of sputum per diem; constant reiterating cough disturbing sleep. Clinical signs mainly in the right lower lobe, but fine rales on the left also. X rays confirmed main changes in the right lower lobe. On September 19th, 1925, evulsion of the right phrenic nerve was performed. Very great traction force was required, the nerve finally breaking; 10 cm. extracted. September 23rd, 1925: Very little cough or expectoration since operation. Night's rest unbroken by cough. Right dome raised 3 cm. above pre-operative position. This patient was sent by Dr. Elkington, Newport, Salop.

Case 8 (Group 4).—A. S., aged 32. (N.W.S.) transferred from the South Wales Sanatorium by Dr. Watson for the operation. Artificial pneumothorax started on the right side in September, 1924. Collapse greatly interfered with by adhesions. Mesial half of the base of the lung fixed to the diaphragm. In January, 1925, the right phrenic nerve was evulsed; 18 cm. of nerve extracted. The dome was only slightly raised into the thorax; it was immobile during quiet respirations, but showed paradoxical movements on deep respirations. By July, however, radiograms showed that the dome had risen into the thorax a further 2.25 cm. Dr. Watson, writing to me on July 1st, said: "Though it may be little, I think he has made some improvement." Since the evulsion it has been found possible to double the interval between the refills.

Case 9 (Group 4).—Mrs. G., aged 35. (V.C.S.) Admitted May, 1925, with extensive activity and fibrosis all over the left lung and slight involvement of the root of the right lung. Artificial pneumothorax started on the left side in June, 1925. Condition greatly improved by the end of October, when she returned home. In September, 1924, signs of activity present in right upper lobe; the left lower lobe was beginning to creep out. There was also a constant purposeless cough. On February 5th, 1925, left phrenic evulsion was performed; 40 cm. of nerve evulsed; the last 10 cm. consisted of the terminal branches plucked out from the diaphragm. A week later screen examination showed the left dome raised and immobile, except on deep inspirations, when the paradoxical movements were present. The purposeless cough disappeared, and the coughing was reduced 75 per cent. Unlike the last case, in this the evulsion has made no difference between the length of the refills. In neither of them has any obvious alteration in the intrapleural pressures been noticed.

Case 10 (Group 4).—Miss D. R., aged 26. (N.W.S.) Admitted with pleural effusion over the lateral surface of the left lung. Effusion aspirated and replaced by air. The lung fixed in a position of partial collapse by thickened pleura. On June 15th, 1925, phrenic evulsion was done on the right side as the effusion kept recurring; 13.5 cm. of nerve evulsed. On June 15th, much better; was eating and sleeping better. On July 31st she felt gone, but dyspnoea practically unchanged. Very slow reaccumulation of liquid. Right dome raised 3 cm. above left; no paradoxical movements.

Case 11 (Group 4).—Mrs. S., aged 25. (V.C.S.) Bronchiectasis of right lower lobe. Admitted February, 1925. Artificial pneumothorax done, but partial collapse of base only obtained. On July 18th, 1925, evulsion of the right phrenic nerve attempted. During traction on the nerve the patient experienced pain referred to the right shoulder, and became very restless. The evulsion was therefore abandoned and the nerve was cut as low as possible, 3.5 cm. being excised. On July 25th the right dome was seen to be slightly raised and to show paradoxical movements. A month later, however, the muscle had recovered, and although the movements of the right dome were considerably less than those of the left they were synchronous.

Case 12 (Group 5).—Miss D. E., aged 33. (V.C.S.) Readmitted October, 1924. Evening temperature 102° (rectal). Involvement of all five lobes, the disease on the left side being considerably worse than on the right. General condition bad; thin, emaciated, dyspnoeic. Constant hard "barking" cough, which seemed to shake the left side; vomiting associated with the cough after meals. An attempt to produce a partial pneumothorax on the left side failed. On December 16th, 1924, left phrenic evulsion was done; 10 cm. of nerve extracted. The incessant barking cough disappeared completely. Moreover, vomiting ceased, except as an occasional feature. On screen examination a raised dome was seen on the left side, immobile during quiet breathing, but showing paradoxical movements on deep respirations. The treatment in this case was not done in the hope of preventing the ultimate end-result of the disease, but to give the patient relief from two most distressing symptoms. In this it was and still is successful. Such relief must necessarily influence greatly both the mental and the physical state of the patient.

Case 13 (Group 5).—T. A. M., aged 50. (V.C.S.) The chief symptom was the almost incessant cough, day and night, except when under the influence of drugs. Artificial pneumothorax attempted but abandoned. On December 19th, 1924, evulsion of the right phrenic nerve was performed; 26.5 cm. of nerve extracted. The patient's condition before the operation was feeble; a close watch was kept on his pulse during the evulsion, but no change in the rate or quality was observed at any stage.

A large quantity of sputum was brought up in the ensuing twenty-four hours; after this the cough subsided and the incessant distressing character of it disappeared. A month later the cough had diminished so greatly that there was a bout of coughing about every eight hours, at which time the sputum was brought up; in between there was no cough or expectoration. The temperature was a degree lower. In this case also the object of the operation was attained, in that he was afforded peace from the incessant cough. The arrest of the disease was of a temporary nature only; the patient died in July, 1925.

Case 14 (Group 5).—Miss T., aged 25. (N.W.S.) Symptoms started with dry pleurisy on the left side in December, 1922. Artificial pneumothorax was begun on the left side in August, 1923. Adhesions prevented more than a moderate collapse. Vomiting started in March, 1924. In December, 1924, owing to the severity of the vomiting, the artificial pneumothorax was given up and a phrenic evulsion was done on the left side; 9 cm. of nerve was extracted. The dome was paralysed, but was not much raised. Paradoxical movements were present with deep respirations. She wrote in July that she was in business, and felt "famous."

Cases 15, 16, 17, 18 (Group 6).—In these four cases the phrenic evulsion was done as a preliminary to thoracoplasty for tuberculous empyema. Lengths of nerves evulsed: 11.5 cm., 24 cm., 16.5 cm., and 32 cm.

Cases 19 and 20 (Group 7).—Phrenic evulsion done as a preliminary to thoracoplasty for tuberculous empyema. Lengths of nerves evulsed: 35.5 cm. and 23 cm.

FULL-TIME OVARIAN FOETATION.

BY

L. ERNEST ACOMB, M.R.C.S., L.R.C.P., D.P.H.,
SENIOR HONORARY ASSISTANT SURGEON, ROYAL GWENT HOSPITAL,
NEWPORT, MON.

With X-ray Photographs and Notes by

T. I. CANDY, M.B., D.M.R.E.,
HONORARY RADIOLOGIST TO THE HOSPITAL.

(With Special Plate.)

A CASE of ovarian foetation is sufficiently rare to merit report. The literature of the recorded cases from 1910 to 1917 has been reviewed by Lockyer in vol. 10 of the *Proceedings of the Royal Society of Medicine*; he says that of the 33 cases quoted in the German statistics only 8 were full-time pregnancies. An American authority, however, questions the authenticity of some of these; 17 further cases he classed as highly probable, of which 8 had proceeded to term. The case which is now reported was seen in November, 1924, and the conditions found at the subsequent operation lead to the conclusion that it was a case of full-time ovarian foetation. The patient was submitted to x-ray examination and several excellent skiagrams were obtained of the unborn foetus a few weeks prior to operation.

Report by L. ERNEST ACOMB.

The patient was a married woman, aged 33, of rather slight and small build; she had a normal menstrual history. Though married for six years or so she had not hitherto become pregnant. On November 30th I was of opinion that she was about eight and a half months pregnant. To the best of her recollection her last period occurred at the latter end of January. She complained of distension and considerable pain in the left groin. She found it uncomfortable to lie flat in bed and had to be propped up.

The abdomen was tense but symmetrical and presented the appearance of a normal pregnancy of about eight and a half months' gestation. A narrow crescentic projection could be palpated in the left groin. This projection was slightly movable, but immediately returned to its former position, and I could not decide the anatomical part of the foetus to which this corresponded. On vaginal examination the cervix was small and considerably harder than is usually the case in pregnancy at this stage. It was high in position and displaced laterally. The os was closed. I was unable to determine the nature of the presentation, and decided to make a further examination under an anaesthetic. Again neither the presenting part nor the lie of the baby could be definitely ascertained. It was certainly not a head presentation and all efforts to perform version were unsuccessful.

I referred the patient to Dr. Candy for x-ray examination with a view to obtaining some definite information upon the position and presentation of the foetus. The unusually interesting series of skiagrams which he obtained accompany this report, and his observations upon them are given below. The projection, the anatomical nature of which I had been unable to determine, was found to be due to the acutely flexed cervical spine.

In consequence of the abnormal x-ray findings it was decided to perform Caesarean section. On opening the abdomen (December 29th) I found the foetal membranes lying towards the right side. The uterus itself was in the pelvis and was slightly enlarged, but not much larger than the non-pregnant uterus. The right Fallopian tube was flattened and stretched over the sac, and the tissue of the right ovary was thinned out, constituting the outer layer of the sac. The latter lay above the broad ligament.

A full-time male child, weighing 7½ lb., lying in dark-stained liquor amnii was extracted without difficulty. The skin was soft and slightly macerated. The child appeared to have been dead for two or three weeks. Large vessels coursed between the walls of the sac. There was no difficulty in removing the placenta, but had the child been alive no doubt extensive haemorrhage would have been met with. The sac and the tube on the right side were removed and the abdomen closed. The patient made an uneventful recovery.

Observations upon the X-ray Examination by
T. I. CANDY.

Skiagrams were taken in the following three positions: (1) dorso-ventrally (abdomen nearest film); (2) ventro-dorsally (back nearest film); (3) laterally (profile view). These showed a fully developed foetal skeleton of about eight to eight and a half months' gestation which was lying in an extremely irregular position. The head was above the pelvis and acutely flexed upon the chest. The cervical spine formed an acute projection against the abdominal wall of the mother. The skeleton of the foetus as a whole was observed, from the lateral view, to lie in a much more ventral position than normal. As it could be seen that

there was ample room for the head to enter the pelvis, it was thought that it was prevented from doing so by the presence of a tumour such as a fibroid; but clinical examination ruled out this possibility.

The subsequent findings at operation of a full-time ovarian pregnancy lend exceptional interest to this series of skiagrams. The radiography of the unborn baby is a very recent advance in radiology, and these skiagrams are, in all probability, the first on record of a case of this nature.

As the x-ray appearance of a normal foetus *in utero* is unfamiliar to many, a skiagram of a normal full-time vertex presentation is also shown.

DISAPPEARING DISEASES.*

BY

C. E. S. FLEMMING, M.R.C.S., L.R.C.P.,

BRADFORD-ON-AVON.

WHEN Mr. Levis did me the honour to ask me to read a paper I thought that as I had just completed forty years of life as a qualified medical man I ought to have something to talk about; but I found it by no means easy to find a subject suitable for a society such as this until one day, while perusing the last report of the Chief Medical Officer to the Ministry of Health, I read the figures relating to the death rate of England and Wales, and noticed that it had dropped, during the past fifty years, from 21.4 to 12.2 per 1,000 living, and the question suggested itself. At what points in the wide battle front of disease had death been repulsed, and for which of these successful fights could we claim credit?

My intention is to give my own impressions as to the decline in frequency of the incidence and the severity of attack of certain diseases and morbid conditions, but before doing so I give you some figures published by the Ministry of Health, as they are accurate records of actual facts, and while they deal only with death rates they may be taken as an index of the incidence and the severity of the diseases referred to.

Table showing the Decline in the Death Rates (per 1,000 population) from Certain Infectious Diseases in the Period 1871 to 1924.

	1871-1880.	1924.	Decrease.
Death rate	21.40	12.20	Per cent. 43.0
Infant mortality (1891)	150.00	75.00	50.0
Diphtheria (1891-1900)	0.26	0.06	77.0
Enteric fever	0.32	0.01	97.9
Scarlet fever	0.72	0.02	97.3
Small-pox	0.24	0.00	100.0
Tuberculosis (respiratory)	2.13	0.81	60.0

This table is a striking record of the disappearing in varying degree of a group of widespread and serious maladies. Except that I have never seen, in private practice, a case of small-pox, the figures here shown are, in their general import, in accord with my own experience.

In the defeat of each of these diseases medicine, curative and preventive, may justly claim to have had a share either directly or indirectly, but we must be careful as to the extent of our claim, since the general improvement in the conditions of the life of the people must have had a large influence in the betterment of their health. Except, perhaps, in the case of rabies it is doubtful whether we—the medical profession and those acting on our advice—can demand credit for the immediate, intentional, direct, and entire control of any one disease. We pride ourselves and our health administration on the reduction in the death rate of phthisis; but I would draw your attention to the accompanying chart (drawn up from figures supplied

by the Ministry of Health) for the years 1847 to 1924, which, it must be remembered, records not the incidence of the disease but the deaths. Note the long steady decline. What influence had the Local Government Act of 1875? During the thirty years preceding it the rate per million had declined by 1,000, during the thirty years succeeding it the rate declined by 1,100. Looking at the chart, it does not appear that any decrease in the death rate followed the discovery of the infecting organism, or that any influence has been exerted by sanatorium treatment and the general campaign against tuberculosis which have been so actively carried on during the last twenty years. The only remarkable point is that the rate rushed up in a startling manner during the years of the war, to fall immediately the war ceased.

It may be urged that without all this activity there might have been a stop in the decline; on the other hand, it may be that the decline is due to a naturally produced immunity of the community, a growing power of resistance to the disease, or the infecting organism may by some natural process be undergoing a change to a less virulent type.

The infectious diseases already noticed naturally occurred to me as the most notable of disappearing diseases, but there are others that present themselves to all of us, in varying degree according to our personal experience. Such, for instance, is gout; how rarely now, compared with forty years ago, does one see a classical case of acute gout. In Bath, the Mecca of the footsore arthritic pilgrim, those who are the high priests of the hydrotherapeutic prophet may have a false impression of the prevalence of gout, though it may be that even they have noticed a falling off in the numbers attending the steamy shrine. Is this decline due solely to dietetic reasons, chiefly to the greatly decreased consumption of port wine and beer, and so only one of the contingent results in the decrease in alcoholism? Surely one of the most outstanding facts in a survey of the last few decades of medical practice is this decrease in alcoholism and all its associated morbid conditions.

How seldom now, compared with thirty years ago, does one have to treat a serious case of acute rheumatism, so-called rheumatic fever; if this is not merely a personal experience, what is the explanation of the diminution in the number of these cases?

In a list of disappearing diseases in ordinary surgery or consulting-room practice I should be inclined to put first anaemia; it seems not long since one was always attending not one but several cases of chlorosis, chiefly, though by no means only, among girls of the servant or working class; now how comparatively rare these patients are. Better conditions of life, of home and workshop, the stopping of child labour, shorter hours of work, better food, more sunlight and air, more rational dress, more outdoor recreation, and last, but by no means least, better teeth—all of these things have, I suppose, been instrumental in this change; and with the decrease in this form of anaemia there must have been a decrease in many conditions attendant on it, such as gastric ulcer, headache, heart failure, and phthisis. Also, I assume, due to the healthier and happier life is the decrease in the number of cases of hysteria, which not long ago were so frequent among the young women whose physical and mental energies were unnaturally restricted. This is the more notable when we realize the apparent increase in so many other morbid nervous and psychical conditions.

Another disease that is much less prevalent is rickets; this is due no doubt to better conditions of life. Here again it may appear to those having charge of the clinics in an orthopaedic centre such as Bath has become that this statement is not justified, but I would like to know the opinion of those in general practice who see these cases in the first instance.

There are many conditions which are much less frequently met with now, which can, perhaps, hardly be described as dying diseases, because they are merely the result of the more effective treatment in an early stage of some disease or deformed condition. Such, for instance, are strangulated hernia, daily becoming less frequent, for the obvious reason that hernias are cured before they become strangulated; peritonitis, which thirty years ago was probably in

* A paper read before the Bath Clinical Society, January 8th, 1925.

CHART SHOWING THE DEATH RATE FROM PHTHISIS FOR THE YEARS 1847 TO 1924.

nine cases out of ten neglected appendicitis; persistent headaches, due to errors of refraction.

Lupus, which is now treated early and successfully, and gastric ulcer, which is now actually cured in hospital by the physician or, failing him, by the surgeon, may be only apparently less frequent, for they, like many other conditions, have possibly, on account of their long duration, given rise to a false impression of their prevalence. For example, one patient with gastric ulcer would require many attendances over a long period of time and leave on the mind of the medical attendant the impression of many cases, with the consequence that when such a case is cured early in its life it may incline one to think that gastric ulcers are less frequent than they used to be.

Again, there are some conditions that may appear to be less frequent because it is no longer fashionable to look for them or to talk about them—such, for example, as movable kidney and displaced uterus, both at one time the delight of the seeker after sympathy and for the doctor dividend-earning ailments. So, no doubt, in due time "blood pressure" will become a less fashionable and less prevalent complaint.

Although it is not a disease, I almost think that we might add to the list of disappearing diseases senility; if it is not disappearing there is much evidence that its onset is postponed by several years.

There is little profit in merely registering the fact of the decline of a disease unless at the same time we can form some idea of the causes of that decline; in the case of the zymotic diseases this is not so difficult, though it is by no means easy to assess the value of the part played by the different agents. It is at any rate obvious that each section of the medical profession—the laboratory worker, the clinician, and the public health administrator—has had an important share in the campaign. Medicine in the fruition of its work has been helped by the State; the State has been dependent on the medical profession, but the brunt of the battle has fallen on the medical man, who has had for long weary years to educate and to persuade an unwilling, an unbelieving, and a not always grateful, public that if only it will listen and help it may be relieved of many of its ills.

With the good old times, whose passing many lament, have passed diseases and conditions of life that none can want back; with improving medical knowledge and service and conditions of life we may look with hope to the disappearance of still more diseases.

Are we ever justified in concluding that any diseases naturally get less virulent and then disappear? What is the reason of the undoubted milder type of some of the infectious diseases—such, for example, as small-pox? Is it due to vaccination and an inherited immunity? If so, why in the recent epidemic in Gloucester was there no difference in the character of the disease in the unvaccinated, whether they were the children of vaccinated parents, or of one or two generations of unvaccinated parents?

Why is it that scarlet fever has become so much less serious? There can be no question of artificial immunity, and one can hardly think that the mere isolation of some of the cases can account for this alteration. Although, judging by the analogy of diphtheria, it may be argued that isolation may have some influence in affecting virulence, the earlier cases in an epidemic of diphtheria are

generally of a very mild type; as the epidemic increases the type becomes more virulent; if, however, the earliest cases are effectively treated and isolated there is not the same increase in virulence.

Is not the disappearance of an infective disease due to altered conditions which render its continuance difficult? Given the old conditions, would it not reappear?

Are we to look forward to a time when, having been freed from all diseases, we shall, like the antivaccinators, lulled into a false sense of security, forget the forces that drove them out, and, relapsing into the old conditions—an unprepared, a non-immunized, and non-resisting community—be attacked with devastating effect?

MEDICAL, SURGICAL, OBSTETRICAL.

THE PREDIVERTICULAR STATE AND DIVERTICULOSIS.

THE recent interesting article by E. I. Spriggs and O. A. Marxer (January 23rd, p. 130) throws a considerable light on the etiology of diverticulitis of the sigmoid colon. The fully developed condition is well recognized by surgeons, but no satisfactory explanation of the train of events which leads up to the formation of the sacculi has been given previous to the report of Marxer in 1923. A recent case in which I have had the opportunity of seeing the colon at operation confirms and amplifies the observations they record in the article mentioned above.

The patient, a man aged 43, had suffered from the passing of loose motions for three or four years; in the latter part of this period he occasionally passed a little blood. Latterly he had a little vague discomfort in the left iliac fossa, but continued to work till brought to hospital, alarmed by the blood in his motions. He was sallow and anaemic. On abdominal examination a somewhat tender spastic colon could be felt in the left iliac fossa; by the rectum the mucosa felt velvety and inflamed. A barium enema of 70 oz. was given without pain, and the picture had all the characteristics mentioned by Spriggs and Marxer: passing out of the ampulla of the rectum there was a length of colon going for some four inches upwards and to the left. This segment was narrowed and its edges presented that peculiar spiky condition so well shown in their illustrations. The radiograph of this length of bowel conveyed to the eye the sense of a rigid walled tube with weak areas in it and contrasted strongly with the distensible colon, into which it passed above, which had the bold curves normal to the bowel.

Sigmoidoscopy was done, but the tube could not be introduced past the rectum owing to pain and inability to distend the bowel properly, while the view was constantly spoiled by blood-stained mucus coming from the bowel above. Laparotomy was performed under spinal anaesthesia. The sigmoid colon, on examination, showed no gross changes, no sacculi, no excessive deposit of fat, no narrowing. Its walls were rather thicker than normal, however, and the areas between the longitudinal bands showed a peritoneum that was distinctly injected and a little oedematous.

C, Caecum. R, Rectum. S, Sigmoid.

While under examination a most extraordinary sequence of events occurred, which in my experience is quite unique. At one point the bowel suddenly narrowed to half its previous diameter; this narrowing spread up and down for three or four inches, the bowel in this area becoming the size of the index finger and quite as firm. It was so rigid that it resisted flexion like a string of large beads very tightly threaded. While the spasm lasted many tiny sacculae appeared between the longitudinal bands; these were each segments of a circle about a third of an inch or less in diameter and lay regularly like beads along the sides of the gut. In a few seconds the spasm passed off and a nearly normal bowel remained with faint evidence of the tiny projections indicated for a few seconds by the altered blood supply at their sites owing to the tension to which the peritoneum had been subjected. The cycle of spasm repeated itself thrice during the time the abdomen was open.

In the absence of any real indication for removing the bowel, appendicectomy was performed in order to allow of local treatment of the mucosa, which from the presence of blood and mucus was evidently inflamed.

This case would appear to be an example of the pre-diverticular state and presents the clinical and radiographic picture that Spriggs and Marxer have described; they emphasize the part that infection plays in preparing the bowel wall, but do not put stress on the second factor which this case exhibits so well—the remarkable local spasm which would appear to be the second link in the chain. The third incident, the herniation, may or may not appear. One sees from time to time cases in which a length of the colon appears rigid and fibrous without diverticula; in these cases the infection would appear to have gone on to fibrosis without herniation. As to whether the tiny projections seen at operation were incipient herniations, I think they were too regular in size and position for this to be the case. Their appearance makes it more probable that they were due to local spasm of the coats of the bowel producing minute haustra like those normally seen on a larger scale in the colon higher up. The sacculae in diverticulitis are variable in size and irregularly situated and for the most part have narrow necks.

In another case of mine with definite sacculae of considerable size the same oedema and injection of the bowel wall was present, and whilst the bowel was being handled a tiny diverticulum, so thin-walled as to be translucent and not more than 4 mm. long by 2 mm. in diameter, shot out like a glove finger when the bowel was squeezed, only to relapse as the pressure was relaxed. This tiny thin-walled sacculae, appearing and disappearing with spasm and relaxation, would seem to be a further stage in the evolution of a diverticulum.

The sequence of local infection of the bowel wall and violent local spasm followed by herniation appears to offer a logical explanation of the etiology of a condition which has hitherto been somewhat baffling to those accustomed to meet with it.

SEYMOUR BARLING.

THE BLOOD SUGAR IN A CASE OF ADDISON'S DISEASE.

A low blood sugar and a raised tolerance are to be expected in Addison's disease, but it appears that very few actual determinations have been recorded. For this reason I venture to submit the following case. The patient was in the Radcliffe Infirmary, Oxford, under Dr. Waters, to whom I am indebted for permission to make the blood sugar estimations.

A married woman, aged 35, with four children, presented most of the classical signs and symptoms of Addison's disease. In January, 1925, she began to suffer from diarrhoea and some abdominal pain, and the menses ceased. These symptoms persisting, she was admitted to the Radcliffe Infirmary. When seen in June, about a fortnight before her death, she was thin and wasted, though not suffering from extreme asthenia. Her skin, which, she said, had always been somewhat dark, was everywhere deeply pigmented except upon the dorsal surfaces of the feet. The buccal mucous membrane was pale, and not pigmented. The chest showed no abnormalities. The abdomen was enlarged, especially in the lower part, and several small masses were felt near the umbilicus; no ascites was present at the time of examination, though shifting dullness had been noted on admission. The systolic blood pressure had been recorded on several occasions and lay between 88 and 100 mm. of mercury. Some fever was present. The urine contained a trace of albumin. The faeces had been examined once for tubercle bacilli, with a negative result, and a blood count had given the following figures: red blood corpuscles 4,220,000, white blood corpuscles 7,600, haemoglobin 52 per cent., colour index 0.6. The diagnosis was Addison's disease, secondary to tuberculous peritonitis.

A glucose tolerance test was made out on June 12th. The fasting blood sugar was 0.08 (grams per 100 c.cm.). This is low, the normal being 0.09 to 0.11. After taking 50 grams of glucose, the figures obtained were as follows:

Time after Glucose.	Blood Sugar.
30 minutes 0.11
45 minutes 0.11
1 hour (spoiled)
1 hour 30 minutes 0.11
2 hours 0.08

No glycosuria resulted. The treatment included injections of adrenalin, but none were given for twenty-four hours before the test.

Although one determination was spoiled, the remainder are quite sufficient to show that the sugar tolerance curve is remarkably flat, in accordance with a raised tolerance for glucose. Maclean's method was employed; as regards accuracy, a large number of control estimations, using standard glucose solutions, had shown my mean error to be ± 5 per cent., with a maximum error of ± 10 per cent.

The patient died rather suddenly on June 26th. There was no autopsy.

I desire to thank Dr. Waters for allowing me to examine and report on this case.

E. F. CHAPMAN.

A NEW OCCUPATIONAL BURSA ("DUSTMAN'S" BURSA).

MANY occupational bursae have been described—the housemaid's, the miner's or student's, the porter's, and others—but for the first time

I have recently seen one due to the occupation of a dustman. It will be observed that a dustman not infrequently has a short ladder by the side of his dust-cart, and that he mounts two or three rungs of this, and then leans with the upper third of his tibia against one of the higher rungs, so as to get a purchase to enable him to tilt the dust from the receptacle into the cart. The accompanying photograph shows the condition better than any description. On the left leg will be seen the adventitious bursa, while on the right leg will be observed the roughened skin at the site where the intermittent pressure has been applied.

W. MCADAM ECCLES, M.S.Lond., F.R.C.S.,
Surgeon to St. Bartholomew's Hospital.

RASH FOLLOWING BARBITONE-SODIUM.

BARBITURIC acid or its derivatives are so much used now as hypnotics that the record of a very marked rash following comparatively small doses may be of interest.

The patient, an adult, was given 10 grains of medinal (barbitone-sodium) every night for three nights, after which a rash appeared on the extensor surface of the arms and legs below the knee. The rash was dark red and papular, and accompanied by considerable itching. As the use of medinal was not then associated with the rash it was continued for three more nights, making a total dose of 60 grains in six days. The result of this was that the rash became more marked, and there was oedema of the parts affected, but the rash did not spread beyond the situations described.

On reading in Martindale's *Extra Pharmacopoeia* that the barbitone series "may produce erythema" the drug was discontinued, and the rash started to fade, disappearing in seven days, with slight desquamation.

P. W. MATHEW.

SACCHARIN IN DISPENSING.

DURING the late war saccharin came into considerable prominence as a substitute for sugar; nowadays it is occasionally given to diabetics as a sweetening agent for tea, coffee, etc., but otherwise it never appears, so far as I can ascertain, to have been used in therapeutics. It occurred to me that its intense and "penetrating" sweetness (said to be 500 to 600 times that of sugar) might be employed to useful purpose for modifying the bitterness of many commonly used drugs. I therefore selected a series of preparations notorious for their disagreeable (and, more particularly, bitter) taste, and tried the effect of adding small quantities of saccharin. The results were encouraging: even added by itself it always produced marked improvement where bitterness was the principal objectionable feature; in combination with various flavouring agents it proved to be a valuable supplement. For example:

Magnesium sulphate: 0.3 grain of saccharin added to 1 drachm in an ounce of water produced a solution hardly distinguishable from sugar and water; 0.15 grain added to an ounce of "white mixture" made this preparation far more palatable.

Paraldehyde: 0.6 grain of saccharin added to 1 drachm in an ounce of water produced a marked improvement in taste. In combination with the juice of half a lemon it provides, I think, the most satisfactory method yet suggested of administering this nauseous drug.

Cascara sagrada (liquid extract): It was found necessary to add 2 grains of saccharin to a drachm (in an ounce of water) before any marked improvement was shown; even then the result was not satisfactory. After partly disguising a drachm of cascara with liquorice and glycerin, however, a grain of saccharin proved to be a valuable addition.

Quinine: Small quantities of saccharin (0.6 grain to each dose) made a welcome addition to various liquid preparations of quinine.

In the case of drugs owing their disagreeable character rather to "flavour" than to "taste," I was not surprised to find that saccharin was of comparatively little value—for example, tincture of valerian was scarcely improved. Creosote, however, in spite of its marked "burning" character, was improved by the addition of 0.6 grain of saccharin to every 3 minims.

For the purpose of disguising the bitter taste of certain medicines, therefore, it would seem that in saccharin we have an agent of which we might well make greater use. It is cheap, innocuous, does not (so far as I am aware) possess any serious incompatibilities, and is readily soluble in warm water.

T. W. PRESTON, M.B.

Reports of Societies.

FOCAL SEPSIS.

At a general meeting of Fellows of the Royal Society of Medicine on February 15th, with the President, Sir STCLAIR THOMSON, in the chair, a discussion was held on focal sepsis as a factor in disease.

Professor G. R. MURRAY, in opening, referred to the increased attention which had been drawn to the subject of focal sepsis within recent years, and proceeded to deal with the modes in which such infection could initiate or affect the course of a malady, illustrating his remarks by suitable cases. In the first place bacteria might be discharged from some focus and conveyed mechanically to some other place. Secondly, bacteria might overcome local resistance at the focus of infection and be conveyed by the lymphatics to the nearest gland, which might arrest further progress, or they might pass direct into the blood stream from the septic focus or after the defence of a lymphatic gland had failed. Once in the blood stream bacteria might multiply and cause septicaemia, they might multiply only at some local spot, or without gaining any real footing they might produce slow but progressive changes in certain organs. Thirdly, bacteria might remain at the focus of infection and influence the body by their toxins which were absorbed. Examples of the first mechanical process were seen in the spread of infection by the fingers in cases of furunculosis, and in the way in which bacteria in the mouth could travel, for example, up Stenson's duct, or be swallowed and produce such lesions as gastritis and colitis, or be inhaled and produce, for example, gangrene of the lung. Direct absorption of bacteria into the blood stream gave rise to

the terrible cases of *post-mortem* septicaemia, or in some cases the organisms seemed to favour some particular spot for multiplying, as in malignant endocarditis. Professor Murray then dealt with the connexion between dental sepsis and arthritis, emphasizing the importance of root abscesses, which might be overlooked if the teeth were not carefully skiagraphed. He quoted Rosenow's work, which went to show that non-haemolytic varieties of streptococci produced fibrositis at points of muscular insertion, and referred to the relation between oral sepsis and severe anaemias. Certain work indicated that the organisms responsible for focal infection were selective in the tissues they attacked, and Professor Murray suggested that it might be a question of the oxygen and food supply available. Considering the large number of organisms present in the mouths and intestines of normal individuals, he thought that there must be some sort of acquired tolerance to these organisms in many cases. He referred briefly to the relation between focal sepsis and nephritis, and then described some cases where the continued absorption of toxins from empyemata had led to early amyloid change or to extensive clubbing of the fingers, which disappeared when these foci were effectively drained. Coming to the question of treatment, Professor Murray pointed out that the eradication of a septic focus was not altogether free from danger. He mentioned some interesting work in connexion with the effect of dental sepsis on the nursing mother, where feeding difficulties could be largely overcome by adequate dental treatment. Certain of the endocrine glands seemed to be affected by sepsis. Focal infection would certainly aggravate and retard the cure of such conditions as exophthalmic goitre, and acute pancreatitis might sometimes be the result of oral sepsis. Professor Murray referred briefly to the problem of systemic infections, such as infection of the bronchi or genito-urinary system, and with regard to intestinal stasis said that he believed it to be far less frequently the cause of disease than some authorities would admit. In summing up, he pointed out that the foci of infection could usually be found in the head, diverticula of the alimentary canal, or genito-urinary passages, while the organisms mostly concerned were either micrococci or members of the *B. coli* group.

Mr. HERBERT TILLEY dealt with chronic focal sepsis in the nose, ear, and throat. He described the paths of infection as direct, as by ingestion or inhalation, and indirect by the lymphatics or blood stream. Dealing first with the faucial tonsils, he defined a "septic tonsil" as one which had suffered from recurrent attacks of inflammation, and was associated with enlargement of the tonsillar lymphatic glands in the neck. The size of the tonsils was not of so much importance, since buried small tonsils appeared to be particularly liable to give rise to systemic infection. From the pathological point of view septic tonsils were associated with excess of polymorphonuclear leucocytes on the surface or in the substance of the gland, the presence of bacteria or debris in the gland not being of such great importance. Mr. Tilley described a striking case of chronic toxæmia completely cured by enucleation of "septic tonsils," and quoted Dr. F. J. Poynton's remarks with regard to the relationship between tonsillar infection and rheumatism in children. He described the various lesions which were produced by tonsillar sepsis, and then dealt with infection of the paranasal and accessory sinuses. It was only within the last few years, he said, that the infection of these sinuses in children had been adequately recognized, and the symptoms produced were very like those of chronic tonsillitis and explained those cases in which symptoms persisted after tonsillectomy. A great deal of pus could be swallowed from an infected sinus in the course of the day, and hence alimentary tract infections were commoner in these cases, and chronic cachexia, often closely simulating malignant disease, was often present. He referred to some work which went to show that cases of lobar pneumonia frequently had infection of the nasal sinuses, and suggested that this would explain the occurrence of cerebral abscess in cases of bronchiectases, since the nasal sinuses appeared to be frequently involved in this disease. He urged that physicians should constantly bear in mind

the possibility of nasal sinus infection, especially when the patient described his symptoms as those of post-nasal catarrh.

Mr. F. W. BRODERICK discussed the dental aspect of the problem. He had been struck with the large number of patients with peri-apical absorption who were yet in perfect health, and on the other hand he had seen great improvement in sick people after such teeth were treated. It therefore appeared to him that the main problem lay in the patient's defensive mechanism. In this connexion he referred to recent work, and showed that defensive measures on the part of the body were largely controlled by the autonomic-endocrine system, so that both a septic focus and a general upset of bodily metabolism might be due to an endocrine or nervous cause. Hence in cases of arthritis, for example, both the joint condition and the septic teeth might be due to the same cause, and the focal sepsis act by still further depressing the action of the defensive mechanism, leading to a vicious circle best broken at the point of dental or tonsillar sepsis. Mr. Broderick quoted some interesting work with regard to the formation of granulomatous tissue at the apex of a tooth, this being a definite defence process, and pointed out that both dental caries and pyorrhoëa could now be explained on a general rather than on a local pathology.

Dr. F. G. THOMSON dealt with the relation between rheumatoid, or, as he preferred to call it, focal arthritis and focal sepsis, and emphasized the importance of treating such sepsis early in the disease. He pointed out that such cases frequently showed absolute or relative absence of free hydrochloric acid in the stomach.

Dr. T. C. GRAVES described the influence of focal sepsis in the production of mental disease, and showed some striking photographs of cases improved by dealing with such infection and by the administration of calcium.

Mr. G. A. PEAKE, speaking as a practising dentist, described certain cases where dental treatment had improved general disorders, but on the whole he had been dissatisfied with the results of such treatment. With regard to dental sepsis and mental disease he had not been satisfied that improvement followed treatment, and he pleaded for a cessation of the prevailing practice of general extraction in almost any disease.

The PRESIDENT showed four temperature charts to illustrate how very acute sinus infection might be, and Professor MURRAY briefly replied.

PSYCHIATRY.

A MEETING of the Psychiatric Section of the Royal Society of Medicine was held in the Central Laboratory of the London County Mental Hospitals on February 10th, on the invitation of Dr. F. L. Golla, the director of the laboratory. Dr. R. H. COLE, the President of the Section, was in the chair, and about forty members and visitors were present. Exhibits by Dr. Golla and his staff of recent methods of investigation were demonstrated, and pathological specimens were shown by Dr. LOVELL and others.

Dr. LANDIS showed the electro-cardiograph and the effects on the tracing of emotional stimulation in psychotic and normal subjects. He also demonstrated an apparatus for recording continuous blood pressure and the effects of various stimuli. Dr. S. MAXX showed various forms of apparatus for determining basal metabolism. Dr. ISABELLA ROBERTSON showed colorimetric methods for determining the hydrogen ion concentration in blood and urine, and the variations seen in certain abnormal cases; she also demonstrated the Van Slyke apparatus for basal alkalinity and a new model for alveolar air estimation. Dr. SHEPHERD showed the Pachon recording apparatus for estimating the blood flow in the hand, and the effects of emotion on this. Dr. LOVELL showed specimens of pancreas and the brains from cases of encephalitis lethargica, and also of certain anxiety and melancholic cases. The slides and microphotographs from the pancreas in the two conditions showed similar inflammatory changes, and Dr. Lovell suggested, from this and other work, that this pancreatic insufficiency might be the predisposing cause rendering the patient liable to cerebral infections and other

lesions. Considerable discussion followed on this, in which Dr. J. R. LORD, Dr. COLE, and others took part. Dr. CLOAKE suggested that the pancreatic and other endocrine disorders might be due to sympathetic lesions following disease of the centres around the third ventricle. Specimens of tumour shown by Dr. GOLLA and others were also discussed, and Dr. COLE quoted a case similar to one shown which had also exhibited few signs during life.

Dr. LORD and Dr. NICOL showed a case of porncephaly which exhibited comparatively few signs in life. Dr. BRANDER showed slides of a pituitary gland from a case of the Lorain type of infantilism in which the anterior lobe alone was affected.

Owing to lack of time discussion was only possible on a few of the subjects exhibited. Dr. COLE, in closing the meeting, proposed a vote of thanks to those who had shown material, and said he felt this type of pathological meeting had proved very successful.

BACTERIAL HAEMOLYSINS IN PERNICIOUS ANAEMIA.

At a pathological meeting of the Leeds and West Riding Medico-Chirurgical Society on February 5th, Mr. A. J. WHITEHEAD, the President, in the chair, Professor J. W. McLEOD and Dr. BERTHA WHEATLEY communicated a joint paper entitled "The importance of bacterial haemolysins in pernicious anaemia."

Professor McLeod said that the emphasis recently laid on the importance of achlorhydria in pernicious anaemia had awakened fresh interest in the bacterial haemolysins as possible factors in the development of this disease, since an increased bacterial content of the upper bowel in achlorhydria had been accepted by everyone who had investigated the point. The observations on which the paper was based had been made with the help of Dr. W. MacAdam in obtaining duodenal fluids by means of the Einhorn tube. Twelve cases of pernicious anaemia and several cases with normal or hyperchlorhydric gastric juice, as well as one or two achlorhydrias without anaemia, had been investigated. The general impression obtained by examining both fresh and heated blood agar plates inoculated from these fluids was that in all achlorhydrias the duodenum contained large numbers of bacteria, among which the pharyngeal and bowel types were fairly evenly represented. No actively haemolytic streptococcus was ever isolated, although the common types of mouth streptococcus which gave slight haloes of clearing on blood agar plates were usually present. The two haemolytic bacteria found were the haemolytic haemoglobinophilic bacterium of Pritchett and Stillman and the *B. welchii*. The first was found more often; but *B. welchii* produced a more powerful haemolysin. Professor Adrian Stokes in this country, and Moench, Kahn, and Torrey in America, had recently drawn attention to the markedly increased content of *B. welchii* in the faeces in pernicious anaemia. Unless a specific parasite responsible both for the achlorhydria and the anaemia existed it would seem likely that *B. welchii* played the chief part in producing anaemia when once the bowel and throat bacteria had invaded the jejunum and duodenum. Difficulties existed in regard to the role of *B. welchii*, however, since injections of Welch toxin induced an increase in the polymorphonuclear leucocytes and also, after a short time, immunity.

Osteomalacia.

Dr. F. S. FOWWEATHER read a paper entitled "Some remarks on osteomalacia, with special reference to a recent case." He stated that a careful blood and urine analysis made recently in connexion with a patient in the Leeds General Infirmary showed the existence of a moderate degree of acidosis, together with evidence of deficient absorption from the alimentary tract. The acidosis was shown to be a "starvation" acidosis, believed to have resulted from chronic malnutrition, and probably due to a qualitative diet defect. The relation between acidosis and calcium loss was discussed. Other workers who had found a connexion between osteomalacia and chronic malnutrition were quoted. The relation between diet defects and the war-time cases of osteomalacia in Europe was noted,

and attention was drawn to the work of Cramer, who believed that deficient absorption due to atrophy of the intestinal mucosa was a result of vitamin deficiency. The tendency to acidosis during pregnancy was put forward as an important factor in the onset of osteomalacia in the under-nourished. Rickets and osteomalacia were stated to be due to the same causes operating at different periods of life.

Amino-acids and Bacterial Growth.

Dr. J. GORDON read a paper on the influence of amino-acids on bacterial growth. Fourteen different amino-acids had been investigated separately with regard to their effect on the growth of bacteria in concentrations from 0.1 to 1 per cent. in 1 per cent. peptone broth. No marked effect was observed on the growth of bacteria, such as *B. coli* and the staphylococcus, which constantly grow freely in peptone broth. Such of the more delicately growing bacteria as were tested were distinctly influenced by some amino-acids, and by this criterion the amino-acids might be divided into three groups: (a) *Indifferent amino-acids*—arginine, glutamic acid, histidine, leucine, lysine, tyrosine, and valine. (b) *Favouring amino-acids*—taurine, aspartic acid, and alanine. (c) *Inhibitory amino-acids*—cystine, glycine, phenylalanine, and tryptophane. In the absence of serum or blood those media with a basis of tryptic digest were inferior to peptone broth for growing delicate bacteria; such media could be improved if a considerable part of the amino-acid was removed by butyl alcohol extraction.

Demonstration of Specimens.

Dr. MOLL (Leeds), in association with Dr. C. W. VINING, showed an example of a Meckel's diverticulum 2 ft. 9½ in. long. The diverticulum had become displaced from its normal anatomical relation with the small intestine; it ran parallel for the whole of its course with the small intestine, and was firmly and physiologically adherent to it. The whole specimen had the appearance of several feet of double intestine. Dr. Moll had been unable to find a similar case in the literature. He presented a diagram showing the process by which he suggested that the diverticulum had been displaced from the antimesenteric border of the small intestine. Dr. MAXWELL TELLING had never seen such a specimen before, nor was he aware that "doubling" of the small intestine occurred at the particular part of the gut.

Mr. CARLTON OLDFIELD (Leeds) showed a case of ovarian pregnancy. He described the specimen, and by means of a slide he demonstrated the corresponding very early ovum and embryo. Mr. Oldfield reviewed the whole subject of extrauterine gestation, and gave an historical account of its place in obstetrics since the time of Lawson Tait. He recounted the examples met with recently, with special reference to the incidence of true ovarian gestation and its significance, and gave the clinical details of the case under discussion. Dr. E. O. CROFT (Leeds) continued the discussion, and gave an account of his experience in the matter of ovarian gestation.

THE MALARIA TREATMENT OF GENERAL PARALYSIS.

At a meeting of the Liverpool Medical Institution on February 4th Professor WARRINGTON YORKE read a paper on the malaria treatment of general paralysis of the insane.

Professor Yorke commenced by pointing out that the treatment of neuro-syphilis could be divided into specific and non-specific. With regard to specific and anti-syphilitic treatment, he was of opinion that the numerous modern intrathecal and other methods of medication were little better than the older treatment with mercury ointment; he felt, however, that it was probable that tryparsamide might prove to be as effective in syphilis as it had been in sleeping sickness. With regard to non-specific treatment, he reminded his audience that Hippocrates and Galen knew that fevers influenced psychoses, as also did Boerhaave and Sydenham. In the middle of the nineteenth century attempts had been made to produce

changes in cases of general paralysis of the insane by the induction of abscess formation and other similar processes. Later, there followed in succession treatment by the injection of non-bacterial substances, such as milk, then the use of vaccines, and ultimately, in 1917, the injection of living micro-organisms. In 1920 Wagner-Jauregg, in Vienna, published the results of the treatment of a series of cases infected with malaria. The technique was comparatively simple, the blood from a malarial individual being introduced into the patient either intravenously, intramuscularly, or by scarification. Professor Yorke advised that the patient should be allowed to have eight or twelve malarial attacks; it was difficult, and needed experience, to decide when the attacks should be stopped. If they were stopped too soon no benefit would ensue; if they were allowed to go on too long the patient might die. There was no means of modifying the severity of the attack; the premature administration of quinine completely spoiled the results and also prevented reinfection for a period of many months. The investigation of 400 cases treated in Vienna during the years 1917 to 1922 showed the following results: complete remission 33 per cent., and partial remission 14 per cent. In a series of 299 cases treated in 1922 in five large British mental hospitals, 70 patients had improved to such an extent that they could be discharged from hospital. In a series of cases in the pre-asylum stage, complete remissions were obtained in over 30 per cent. The latter group obviously contained a larger proportion of cases in the early stage of the disease. It was unfortunate that in many cases the condition was only arrested and the victims still remained useless members of society. At the same time, many such cases became cleaner in their habits and consequently easier to nurse. It was impossible to forecast the result of malarial treatment except that greater success could be expected in early cases. In some cases the improvement was immediate and dramatic, whereas in others it was slow and might go on for months. As regards the effect of the treatment on the serum and cerebro-spinal fluid reactions, these might become normal, but in many cases they were not parallel with the clinical changes; clinical improvement might be complete, while the pathological reactions remained unchanged for a considerable period and only after many months gradually moved in the normal direction. Several pathologists had had the opportunity of examining the brains of remitted cases who had died from intercurrent disease; it was most interesting to note that some of them showed no changes recognizable as those of general paralysis of the insane. Professor Yorke then referred to the opportunity that treatment of these cases had given for studying closely the phenomena of malaria. He pointed out that in these induced cases very few doses of quinine sufficed apparently to cure the patients, in contrast with the difficulty of producing this result in ordinary tropical practice. It had also been possible to establish definitely the existence of three species of malaria parasites, the parasites of each species always breeding true. In the induced cases relapse was comparatively rare, and, when it did occur, long delayed. The ineffectiveness of quinine to cure the war cases and patients in tropical practice was due to the fact that they were not primary infections. The factor which governed relapse was the patient's individuality; the occurrence of relapses was in no way related to the strains of parasites with which the patients were infected, to the drugs used, or to the dosage and method of administration. He advanced an hypothesis of the process by which quinine indirectly destroyed the parasites, and concluded by pointing out the uselessness and the actual danger of either too large doses or of too prolonged administration of quinine.

Spontaneous Dislocations of the Hip.

Mr. R. WATSON JONES read a paper on spontaneous dislocation of the hip. In a series of 6,000 patients there were 27 spontaneous dislocations of the hip resulting from infantile paralysis, spastic paraplegia, and various forms of acute arthritis. After emphasizing the important part played by muscular action in the stabilization of joints, and indicating that the action of ligaments was essentially subservient to that of muscular control, it was shown that

precisely the same derangement of muscular balance existed in all types of spontaneous dislocation. There was always an overaction of the flexor and adductor muscle groups, this being due to paralysis of the antagonists in poliomyelitis, to spasticity of the muscles in cerebral paraplegia, and to reflex muscle spasm in acute arthritis. Moreover, the position of flexion and adduction was anatomically the most unstable position of the hip-joint. The rational preventive treatment based on these facts was the maintenance of the extended and abducted position of the hip, and in all cases (except some cases of arthritis in which there was complete destruction of the joint) this procedure should be sufficient to prevent spontaneous dislocation. In the consideration of the differential diagnosis x-ray photographs were shown in cases of congenital dislocation coincident with poliomyelitis, spastic paraplegia, and even suppurative arthritis.

THE VALUE OF RENAL FUNCTION TESTS.

At a meeting of the Newport Medical Society on January 27th, the President, Dr. S. HAMILTON, in the chair, Lieut.-Colonel W. K. BEAMAN read a paper on the value of renal function tests in clinical medicine. He began by pleading for closer co-operation between the clinician and the biochemist or pathologist, and said that the pathologist had done great things although handicapped in the past by this lack of co-operation; in the newer biochemical research co-operation was essential. He then touched shortly upon the general methods in use at the present time for the estimation of renal function, and for general use he recommended the urea concentration test of Calvert, which was a modification of Maclean's original urea concentration test. Lieut.-Colonel Beaman stated that after considerable experience of this test he placed the greatest reliance upon it, and believed it to have a very wide sphere of usefulness. He described its value in surgical cases, especially in cases of obstruction to the flow of urine, as exemplified in enlargement of the prostate. In obstetric work—for instance, in cases of albuminuria—he claimed that the test was of great value in indicating those cases of nephritis complicated by pregnancy in which termination of the pregnancy was indicated. In general medical practice he stressed its value in defining the various types of nephritis, and stated that he had found it invaluable in distinguishing cases of pure hyperpiesia from cases of chronic interstitial nephritis. It was in this last respect that he considered the test most valuable, since the diagnosis was often so difficult clinically, and a correct diagnosis was so essential from the point of view of prognosis. He then showed a chart of the findings given by Calvert as typical of the various conditions mentioned, and next a series of charts of certain cases investigated by himself during the past year. These charts brought out very clearly the differences between azotaemic and hydraemic nephritis, and also between chronic interstitial (azotaemic) nephritis and hyperpiesia. He then showed charts of several other renal and genitourinary cases where this test had been of value either from the point of view of diagnosis or as an indication for treatment, and lastly, charts of cases in which the findings were atypical or the diagnosis was still in doubt. He hoped that by continuing investigation in this class of case and combining close clinical observation with the use of this test its value would be further enhanced and its scope made still wider.

OPERATIVE TREATMENT FOR RECTOCELE.

At a meeting of the Edinburgh Obstetrical Society held on January 13th, with the President, Dr. R. W. JOHNSTONE, in the chair, Professor B. P. WATSON read a preliminary communication on his technique for the cure of rectocele.

Professor Watson pointed out that the essential feature in his operation was the isolation of the special fascio-muscular sheet, which supported the rectum and which was deficient in all cases of rectocele. Thus it was that recto-

cele only occurred when this sheet was damaged, but did not occur even when the levator ani muscle and its fascia were badly damaged so long as this rectal fascia remained intact. The fascia lay deep to the levator ani muscle, in close relation to and supporting the anterior rectal wall. It was in intimate relation with the posterior vaginal wall in its middle third, and became continuous at the sides of the cervix with the pubo-cervical layer of fascia—the essential support of the bladder. The operative treatment recommended for rectocele therefore consisted in defining and freeing this fascia and then repairing it after replacing the herniated rectum. The operation was then described in detail and was fully illustrated by lantern slides. The chief point of the operation was the raising of a flap of the posterior vaginal wall by inserting closed scissors midway between the middle line and the limit of the muco-cutaneous perineal incision on either side. The scissors were passed beneath the postero-lateral vaginal wall well to the side of the rectum, and were opened out; in this way the natural line of cleavage was easily found. Dissection was then continued towards the middle line where scar tissue obliterated any definite layers. This scar tissue was easily dissected off the rectum from the sides, and the dissection was carried to the upper limit of the rectocele. As this was done two bands of tissue appeared, which were firmly attached to the under surface of the vaginal flap, and between which, in the middle line, there bulged the rectal wall. These bands were the edges of the torn rectal fascia and, when the dissection was extended to the upper limit of the rectocele, were found to unite in the middle line. This fascia was freed and then united over the rectum with a continuous suture, and by this means the rectocele was cured. The perineum was built up in the usual way. The most important part of the operation was the separation of this rectal fascia from the under surface of the levator ani, which was done by blunt scissors dissection; the fascia could thus be sutured separately and not together with the muscle, which was the usual procedure. By this means there was no tension, thus ensuring better healing and more accurate apposition. The operation was claimed to be more correct anatomically than the usual procedures in cases of rectocele, and had given, in Professor Watson's experience, most excellent results, no recurrence of a rectocele having ever been reported after its performance.

Three Caesarean Sections.

Professor J. A. KYNOCN (Dundee) read a paper on three cases of Caesarean section, which he had performed during the last few years, the operation being required for some unusual occurrence in each case.

The first was an 8-para, who was suffering from severe internal accidental haemorrhage, and was in a collapsed condition before operation was performed. Caesarean section was done as quickly as possible, and on opening the abdomen the uterus was found to be congested and haemorrhagic in appearance, with purple mottled patches here and there. There was concealed haemorrhage in the left broad ligament, and the left Fallopian tube also presented the same haemorrhagic appearance. The child was delivered, and the uterus was stimulated to contract by means of pituitary extract and by hot towel stimulation. This was continued for at least ten minutes before the contractions became satisfactory, after which the uterus and abdomen were closed. Although in a very weak state after the operation the patient made an uninterrupted recovery and left the hospital in three weeks. The case showed that in some cases, at any rate with hot towel pressure and injections, contractions could become so satisfactory that hysterectomy was not required. The second case was one of prolapse of the cord, which occurred in a 2-para, whose first confinement had been difficult on account of a slightly contracted pelvis, and the child, though born alive, did not survive. On admission for the second confinement the cervix was slightly dilated, the cord was found to be prolapsed, but pulsating, and the foetal heart sounds were satisfactory. On account of the contraction of the pelvis Caesarean section was decided upon and a living child was delivered. The third case of Caesarean section was performed in a case of a funnel-shaped pelvis, which Professor Kynoch deemed to be more common even in this country than was generally supposed. In this case the head had remained on the pelvic floor and had been making no progress for four hours: on examination the subpubic angle was found to be so acute that barely two fingers could be admitted. The diameters of the

outlet were: intertuberischial $3\frac{1}{2}$ in., posterior sagittal 3 in. On account of these measurements and the acuteness of the subpubic angle spontaneous or instrumental delivery was impossible, and therefore it was a question whether pubiotomy or Caesarean section was to be the treatment. As the patient was a primipara Caesarean section was decided upon and a 7 lb. child was delivered. Both mother and child made a satisfactory recovery.

Post-partum Convulsions.

Dr. E. CHALMERS FAHMY described a case of post-partum convulsions, which presented great difficulty in diagnosis.

The case was one of a primipara, who was admitted to the Royal Maternity Hospital, Edinburgh, in labour. The first labour had been uneventful, and she had been well throughout the second pregnancy, except for some slight oedema of the feet and legs. On admission the blood pressure was normal, and there was only a slight trace of albumin in the urine. She was delivered spontaneously, and the placenta and membranes came away completely; twelve hours after delivery the patient complained of headache and difficulty of vision. Morphine was given at once, but a fit developed. The usual eclamptic treatment was then administered, but a second fit occurred one and a half hours later. There was albumin (1.4 per cent.) in the urine, but the blood pressure was only 140/98 mm. The patient became drowsy on recovering from the fits, and this drowsy condition lasted for seven days. The blood pressure for these days was never above 130 mm., and the albumin decreased by degrees. On the seventh day after delivery the fits recurred, and within twelve hours she had eleven fits. Lumbar puncture was performed, and some clear fluid under increased tension was withdrawn. No micro-organisms were found in the fluid. There was only a slight trace of albumin now in the urine. The patient again became drowsy, but consciousness returned in a few days, and she eventually recovered completely, being discharged from hospital after a further three weeks' stay. At a subsequent pregnancy a healthy child was delivered, without any signs or symptoms of toxæmia, and during this pregnancy there was no albumin in the urine.

The diagnosis offered great difficulty, and, in Dr. Fahmy's opinion, the fits were due in the first case to eclampsia. This was followed by drowsiness, culminating in fresh convulsions, due, probably, to the brain being affected by the toxæmic condition. Possible diagnoses of hysteria, epilepsy, and a lesion of the brain were ruled out, but it was difficult to exclude nephritic toxæmia definitely; on taking into account her subsequent pregnancy, when no albumin manifested itself in the urine, the presence of the last condition appeared unlikely.

RADIUM.

At a meeting of the London Association of the Medical Women's Federation, held on February 9th at the British Medical Association House, the President, Dr. CHRISTINE MURRELL, in the chair, a paper, illustrated by lantern slides, was read by Professor SIDNEY RUSS on radium and its clinical applications.

After briefly recounting the discovery of radium and the rapidity with which this was followed by experiments relating to its possible therapeutic uses, Professor Russ went on to discuss some of the most outstanding features of its physical properties. He pointed out that it gave off three distinct kinds of ray (alpha, beta, and gamma rays), each of very different penetrative power, and probably of different physical nature. Of these the gamma rays were the most important clinically, as they had the greatest penetrative power. He then dealt with the necessity of control of the rays, and went into the questions of size and shape of containers, the effect of these on the rays, and the intensity of the rays at various distances from the radium tube. The biological action of the beta and gamma rays was next considered. Slides were shown demonstrating the deleterious effect of the rays on cultures of bacteria and on germinating plants. It was this property of inhibiting growth which had led to the employment of radium clinically in the treatment of malignant tumours. Experiments by Webb, Dominici, Chambers, and others were described, illustrating the results of irradiation on carcinoma and sarcoma in animals. For the first few days

the tumour cells appeared unaffected, but soon they disappeared, overcome by the normal tissues of the body. Tumour cells after exposure to radium would not grow if transplanted into another animal. It was, however, shown conversely that under certain conditions normal fibrous tissue might become sarcomatous under the influence of radium, hence the necessity for a more thorough investigation into the problem of dosage. The effect on animal tissues, which possessed the power of repair, depended on the length of time of the individual application rather than on a summation of several exposures. This, of course, was not so in the case of a photographic plate, in which the result of exposure was the same whether the exposure had been made over one long or several short periods. The effect of radium on cells in the growing or dividing stage was described, and reference made to recent experiments in Paris and Brussels. Professor Russ also dealt with the characteristics of the radium emanation or radon, and concluded with a convincing experiment as to its electrical properties; an electroscope was discharged merely by bringing near to it a piece of iron which had been for a short time in contact with a tube of radon.

REFLEX PROCESSES.

On February 9th Dr. BRYSON, in a paper before the James Mackenzie Institute for Clinical Research, St. Andrews, on the functional unit and reflex processes, criticized the prevailing teaching that certain reflex activities were controlled by centres, maintaining that in all cases control from the periphery was the only factor regulating them apart from psychological influence. In a previous communication he had elaborated this view in regard to the cardiomotor and vasomotor reflexes. The functioning of the organs of the body, he said, was regulated according to the requirements of its functional units. The physiological unit consisted of the cell with its capillary supply. The latter could only be efficiently regulated by the cell. The activities of heart and arteries must be determined by the needs of the functional units and be regulated by them. Impulses from these peripheral structures must therefore determine the activities of the so-called cardiomotor and vasomotor centres. The "centre," in fact, was nothing more than a focus of integration for impulses received from the functional units at the periphery. The continued belief in "specific" centres was largely due to the difficulty of demonstrating afferent tracts. This principle of peripheral control acting *through* the central nervous system was incompatible with control *by* the central nervous system, and this applied to all reflex processes. For a reflex to be modified in its course implied that it was imperfect in its design.

The lecturer then discussed the role of sensation, maintaining that between the sensory and motor areas of the cortex intermediate neurones were present, upon which sensation arose and conditioning occurred upon the reflex processes. This he termed "psychical integration." Elliot Smith had shown that as evolution advanced the sensory and motor areas increased in size, but that it was not to these areas that the brain of man chiefly owed its size, but to the part interposed between them. Dr. Bryson illustrated his view by reference to hunger, thirst, exhaustion, and other sensations, and in conclusion emphasized the clinical importance of the study of the relationship of reflex processes to sensation and of the psychological problems involved.

The paper gave rise to an animated discussion, in which Professor DAVID MORRISON, Mr. MACE, and others took part.

THE seventh Congress of the German Society of Urology will be held from September 30th to October 2nd, under the presidency of Dr. V. Blum, at the Billroth-Haus in Vienna, when the chief subjects for discussion will be the pathology, pharmacology, and treatment of anaemia, and the pathology and treatment of malignant tumours of the bladder. There will be an exhibition of instruments, apparatus, and drugs. Further information can be obtained from Dr. Hans Gallus Pleschner, Alsterstrasse 20, Vienna.

Reviews.

PRINCIPLES OF TREATMENT IN EMPYEMA.

PROFESSOR EVARTS GRAHAM of Washington University, St. Louis, is a scientific surgeon, and has again shown this in his recently published essay on *Some Fundamental Considerations in the Treatment of Empyema Thoracis*,¹ which was awarded the Samuel D. Gross prize of the Philadelphia Academy of Surgery in 1920. The delay in its publication has been due to disputes in the publishing business, which previously rendered it impossible to offer the monograph to the public at a reasonable price. Professor Evarts Graham was a member of the Empyema Commission of the United States Army which investigated the high mortality of the cases of empyema which occurred during the winter of 1917-18 in the army camps in America, and were found to be due to a haemolytic streptococcus. The high mortality (30 per cent. on an average, but in some camps as high as 70 per cent.) occurred when the then orthodox plan of operating early on such empyemas was in vogue, and fell (to the very low percentage of 4.5) when the principles enunciated by the Commission and described in the present volume were acted upon. The delay in the publication of this essay has enabled the author to supply in an addendum a most fair-minded reply to the criticism raised, especially by Duval, against the Commission's conclusions.

The three fundamental principles laid down for the treatment of empyemas due to the haemolytic streptococci are (i) to avoid the production of an open pneumothorax in the early stage when the lung is in a condition of influenzal inflammation, (ii) to prevent the production of a chronic empyema by rapid sterilization and obliteration of the infected cavity, and (iii) careful attention to the patient's nutrition. A large number of experiments were made on animals to elucidate the subject of intrapleural tension and on the effect of producing an open pneumothorax when the pleura had been infected; it is noteworthy that comparative determinations of the intrapleural tension in human corpses and in dead animals were made before assuming that the experimental results could be applied to man. The experiments showed that the current conception that the mediastinum acts as a rigid partition so that the lung on the sound side remains unaffected by an open pneumothorax on the other side is incorrect; in reality the intrapleural pressure on the two sides remains about the same, except in old empyemas and mediastinitis when, from the formation of adhesions, the mediastinum does become a more resistant partition; in such cases, therefore, the risk of making a large opening into the pleura is much less than in an acute case. The bad effects of making an open pneumothorax, quite apart from the introduction of micro-organisms, are discussed in an interesting manner. With regard to the second fundamental principle, Dakin's solution of neutral 5 per cent. sodium hypochlorite is most satisfactory, both as a sterilizer and by its solvent action on the exudate and its decorticating effect in leading to obliteration of the cavity.

THE HIPPOCRATIC CONCEPTION.

In an interesting medical historical work on the history of medicine, entitled *Il Volto di Ippocrate*² (the countenance of Hippocrates) Professor CASTIGLIONI demonstrates to us a sound method of gaining a clear comprehension of the evolution of the science. Discarding the common practice of abstracting medical conceptions from their surroundings and tracing their history in isolation through the centuries, he examines them as it were *in situ*. He portrays the social, political, and religious features of successive epochs and shows how closely medical theories are related to and coloured by them. Modern conceptions, indeed, are often merely ancient ideas in a different dress, suited to the philosophical fancies of the time. The foundation of medical science is the same in all ages—

namely, the desire to allerviate human suffering; and the measures employed to that end in any given epoch depend, not only on the stock of knowledge already accumulated, but to a very large extent on the social, political, and religious ideas prevailing at the time. Thus, among the Hebrews we find that their comparatively advanced knowledge of hygiene was due in very small degree to the mere progress of scientific knowledge; on the contrary, it arose as a natural corollary to their religious belief. They held that purity of heart was impossible in a body that was unclean.

Many other instances of an analogous kind might be quoted from Professor Castiglioni's book, such as the organization of the medical profession, and the creation of the science of forensic medicine by those masters in law and organization, the ancient Romans of the late republic and early empire. Fully to carry out the scheme outlined by the author would doubtless require several volumes, and to bring the subject within moderate limits Professor Castiglioni has selected several epochs bridging the period between the times of Hippocrates and our own days. Three chapters are devoted respectively to Hippocrates and the philosophy of his period, the sanitary laws of the Hebrews, and the medical profession among the old Romans. The writings of Dante are utilized to introduce the subject of mediaeval scholasticism and its influence on medical ideas. Similarly the subjects of anatomy and physiology are introduced in connexion with the work of Leonardo da Vinci and Valsalva. In this way a very clear idea is obtained, not only of the actual progress of the science, but also of the reasons for its development in certain directions during certain periods, and for its phases of decadence and renaissance. Three interesting chapters deal with the subjects of venesection, medical journalism, and the chemist's shop, and in connexion with the last named the author has provided a number of beautiful illustrations of Etruscan vases of which he is the fortunate possessor. In addition to these, the book is copiously illustrated by fine reproductions of drawings from the old masters and writers, which contribute greatly to what we consider a very attractive book.

LEWIS'S "CLINICAL DISORDERS OF THE HEART BEAT."

Now in its fifteenth year and sixth edition, Sir THOMAS LEWIS'S *Clinical Disorders of the Heart Beat*³ is a clear and authoritative guide, and, contrary to the general rule, has not increased in bulk to correspond with its progressive reputation; in fact, the present edition is ten pages shorter than the previous one. Although believing that those who are unfamiliar with the new conception of heart disease due to the employment of graphic methods are incompetent to deal with cardiac patients, Sir Thomas Lewis does not suggest that practitioners should be more than cognizant of its principles and deductions, or that they need be expert in taking graphic records. Those engaged in cardiological research and teaching should establish simple clinical means of recognizing conditions the nature of which has been determined by methods demanding technical skill.

The last edition (1921) came out at about the time that Sir T. Lewis's researches on the circus movement of the auricles in auricular flutter and fibrillation (vide Oliver-Sharpey Lectures, *BRITISH MEDICAL JOURNAL*, 1921, i, 551, 590) were published, and these experimental results are embodied in the present volume, which also contains a critical opinion as to the value and future of quinidine treatment; that this drug will come into general use is doubtful, for restoration to a normal rhythm is seldom permanent, and a close control of the reaction is possible only by means of the electro-cardiograph. Paroxysmal tachycardia and the rarer condition of paroxysmal fibrillation are distinguished, and the treatment of the two laid down. In regard to heart-block it is pointed out that, though digitalis often increases the grade of heart-block, this effect is not in itself harmful, and that the

¹ *Some Fundamental Considerations in the Treatment of Empyema Thoracis*. By EVARTS A. GRAHAM, A.B., M.D. London: Henry Kimpton. 1925. (Med. Bro. pp. 110; 15 illustrations. 7s. 6d.)

² *Il Volto di Ippocrate*. By ARTHUR CASTIGLIONI. Milan: Società Editrice Unica. 1925. (Double roy. 16mo, pp. 383; 133 figures. L.60.)

³ *Clinical Disorders of the Heart Beat: A Handbook for Practitioners and Students*. By Sir THOMAS LEWIS, C.B.E., M.D., D.Sc., F.R.S., F.R.C.P. Sixth edition. London: Shaw and Sons. 1925. (Extra post 8vo, pp. xii+131; 55 figures. 8s. 6d. net.)

drug may be given without hesitation and sometimes with benefit.

This valuable handbook may well remind the senior reader of the writings of the late Dr. Samuel Gee, for there is never a word too much, and each word is in its right place and tells with its full value and weight; thus *pulsus alternans* is described as "the faint cry of an anguished and fast failing muscle, which, when it comes, all should strain to hear, for it is not long repeated. A few months, a few years at most, and the end comes."

OPOTHERAPY.

In his book on endocrine therapy⁴ Dr. GUY LAROCHE gives a short and very readable summary of the experimental and clinical evidence which forms the basis for the use of endocrine extracts. He describes the pharmacological and therapeutical actions of preparations of the thyroid, the parathyroids, the thymus, and the suprarenal glands, the gonads, and the islets of Langerhans.

The book is written in a reasonably critical manner, and in his preface the author points out the necessity of basing endocrine treatment on the solid foundations of physiology and pathology. The recent French work in endocrinology is well described, and an interesting feature is a summary of the work of Chauffard, Laroche, and Grigaut, who studied the cholesterol content of the suprarenal glands in health and disease, and showed that this content was very low in infectious diseases and remarkably high in arteriosclerosis. The author considers that these facts point to the suprarenal cortex as being the site of formation of certain lipoids, in particular cholesterol.

Dr. Laroche confines himself to the description of effects for which definite objective evidence can be adduced, and the claims made for organotherapy show a corresponding restraint. About three-quarters of the volume is occupied by a description of the action of preparations of the thyroid, suprarenal, and pituitary glands. The book as a whole should serve as a sound guide to practitioners, and indicate to them what effects may reasonably be expected to be obtained from endocrine therapy.

Dr. MARCEL LAEMMER has produced a formulary of clinical opotherapy,⁵ giving an account of the mode of administration of a very wide variety of organ extracts, including the thyroid, parathyroids, thymus, pituitary, pineal, and suprarenal glands, the spleen, gonads (testicles and ovaries), kidneys, liver (liver substance and bile), pancreas, prostate, mammary glands, stomach, duodenum, brain, spinal cord, heart, lungs, lymphatic glands, bone marrow, bones, muscle, and placenta. In the introduction it is said that it contains "advice and formulae which do not conform strictly to laboratory evidence, but always to clinical experience." The first statement is certainly indisputable. The line of treatment indicated in the volume is exemplified in a series of formulae recommended for a girl of 16 with obesity coupled with retarded sexual and mental development; injections of pituitary extract are recommended, as well as bone powder, brain powder, powdered bone marrow, thyroid and ovarian extract given by mouth in various combinations.

The book gives an account of polyglandular therapy pushed to an extreme, and some may think to absurdity.

HEDONISTIC PSYCHOLOGY.

We gather from Dr. DEARDEN's book, *The Science of Happiness*,⁶ that the main object of life is its achievement, that the pursuit of this ideal is a science, that scientific method involves a knowledge of psychology, and that the object is to be attained by certain mental exercises combined with physical culture and proper feeding. By an intelligent study of psychology, says Dr. Dearden, the lives of all of us can be rendered more happy, healthy, and efficient. Though the increasing strain of existence is

causing life to be fraught with terrible possibilities, a new era has dawned for the sufferer from nervous exhaustion. Therefore, in the italics that Dr. Dearden uses so often, let us *set ourselves intelligently to develop to the highest intensity the mental qualities we possess already*.

The author then proceeds to study the various functions of the mind, and the methods of keeping the central cells in the nervous system in perfect peace; for "it is in the production of this peace of mind that a knowledge of psychology is of such great value." There are chapters on the nature of reactions, habit, instincts, emotions, memory, attention, the will, and reason. The explanation of the working of these functions is accompanied by an account of disorder in their action, and by descriptions of the methods Dr. Dearden recommends for their restoration and maintenance. Thus for the prevention of mental despondency and gloom it is necessary, on rising from your bed, to go to your looking-glass, and force yourself to greet with a beaming smile that curiously complex fellow who is yourself. No matter if the smile is sardonic: do it all the same. This is called the Morning Beam. On the James-Lange theory that the feeling in the coarser emotions results from the bodily expression, the morning beam will set your mind beaming. At various times in the day, certainly in the evening, it is necessary to perform the ceremony of relaxation. You then school your features to take on an expression of peace and happiness, and you go over in this most receptive frame of mind the catalogue of all those circumstances in your condition which should make for cheerfulness. If suffering from insomnia you prepare for the ceremony by taking no solid food for at least two hours before bedtime. Half an hour before retiring you take a glass of hot milk or hot water, not tea, coffee, or alcohol. You then lie back in your chair and go through formal relaxation. Each system of muscles is taken in turn, you see how far you can "let go" from the strained position in which you find them. You imagine yourself sprawling loosely in an attitude of abandon; and, relaxing your mouth in a happy, far-off smile, you make your mind dwell on the great mind of the universe. At intervals during the day your time may be occupied by tackling some of the examination papers which Dr. Dearden attaches to some of his chapters. You may describe the psychology underlying the appeal of the Salvation Army Band or of the three-card trick; or you may puzzle your brain in explaining the value to the individual suffering from nerves of the instinct of curiosity.

Dr. Dearden has thought it well to discuss in a separate section the thorny problem of sex; and, according to the publisher's book-wrapper, he has handled the subject with a boldness and delicacy hitherto unapproached. The sexual act is described, and there are chapters on perversion, self-abuse, impotence, and marriage. With regard to contraceptives Dr. Dearden appears to favour the sheath or condom as the best general method for adoption. In discussing the sexual inactivity imposed upon women Dr. Dearden remarks: "Amongst the so-called 'lower classes' . . . a healthy sexual freedom has been allowed to women which it is assumed will be followed by marriage in the event of a child resulting from the intercourse." How far the practice is general we do not know; but it certainly exists in many parts of rural England. Country doctors, we believe, attend many primiparae within a few weeks of marriage; and the occurrence does not seem to arouse much comment. In some places in the South of England there used to exist a custom called "bundling." Unmarried girls, having been sewn up securely by their mothers in some sort of clothing, were allowed to pass the night with the man of their choice.

Dr. Dearden's book aroused the interest of a well known writer in the *Times*, who raised the question, often debated before, whether, according to the James-Lange theory, the simulation of an emotion aroused that emotion in actors. This question drew replies from Sir Frederick Mott and Dr. C. S. Myers. Quite apart from such questions of detail, it might be interesting to investigate Dr. Dearden's main thesis, and to ask whether the pursuit of happiness is really the main object of existence. Is happiness obtainable, with or without a knowledge of psychology, or must we believe the German author, quoted recently by the

⁴ *Opothérapie Endocrinienne*. Par Dr. Guy Laroche. Paris: Masson et Cie, 1925. (51 x 81, pp. 151, 10 fr.)
⁵ *Opothérapie*. Par Dr. Marcel Laemmer. Paris: Masson et Cie, 1925. (51 x 81, pp. 151, 10 fr.)
⁶ *The Science of Happiness*. By Harold Dearden, M.R.C.S., L.R.C.P. London: W. Heinemann, Ltd, 1925. (Demy 8vo. pp. viii + 341. 10s. 6d. net.)

B.B.C.: "Man may not linger, and nowhere finds he repose; we stay not, but wander, we grief-laden mortals, blindly from one sad hour to another, like water from cliff unto cliff ever dropping?"

And although Dr. Dearden seems to suggest that a knowledge of self would lead to unselfishness, the process of obtaining that knowledge by self-investigation seems to be so arduous that it is doubtful whether much time would be available for more altruistic efforts. Perhaps the fact of the matter is that the healthy, not needing a physician, need not bother to read Dr. Dearden's book or to practise the Morning Beam. The neurotic and the nerve-exhausted, on the other hand, should derive from its perusal as much satisfaction as from the Eleusinian mysteries of modern cults, with a much more healthy effect upon their minds. Dr. Dearden deals with his subject in an entertaining manner; he illustrates his meaning amusingly; and very few of his remarks can irritate anybody.

EVOLUTION AND GENETICS.

A third and revised edition of four lectures delivered in 1916 under the Vanuxem Foundation at Princeton University by Professor T. H. MORGAN, who occupies the chair of experimental zoology in Columbia University, has just been published. The previous editions bore the title "A Critique of the Theory of Evolution"; the title of the new has been altered to *Evolution and Genetics*,¹ not because it is less a criticism of the theory of evolution than its predecessors, but because greater attention is given to the bearing of recent discoveries in genetics and in mutation on evolution. The original four lectures have been subdivided and enlarged into thirteen short chapters; the two last, which deal with the inheritance of acquired characters and the evidence of human inheritance, are entirely new.

In the opening chapter the author exposes the looseness of definition in the use of the term "evolution," and finds essential differences between historical evolution, such as the evolution of the earth or of human inventions, and the biological evolution of organic life. He then proceeds to criticize what he describes as the four great historical speculations regarding the origin of species—namely, the theory of Buffon and St. Hilaire, who attributed changes in fauna and flora to environment; the theory of use and disuse, to which Lamarck's name is attached but which has now few followers among trained investigators in consequence of Weismann's views as to the inadequacy of the evidence that acquired characters are inherited; the theory of orthogenesis, or inner driving force or principle; and Darwin's theory of natural selection. The evidence of organic evolution from comparative anatomy, embryology, palaeontology, and genetics is then discussed. Professor Morgan's view is that at present there is no evidence that withstands the test of criticism in favour of any other origin than that the slighter as well as the larger differences, creating new inherited variations in biological life, have arisen as genetic mutations. This is his standpoint throughout the remaining chapters. He endeavours to demonstrate the advance in the study of evolutionary processes by the discovery of the manner in which new characters appear and are inherited in consequence of the behaviour of the chromosomes of the reproductive cell and their bearing on Mendel's two laws of heredity—the law of segregation and the law of free assortment. This is further developed in chapters on linkage groups and the chromosomes, sex-linked inheritance, crossing over, and the origin of species, in which the element of chance may in some cases be the cause of new mutation characters in the progeny. In dealing with the subject of the inheritance of acquired characters the author attacks the belief that such characters can be or are ever inherited. He attributes its popularity to the willingness to listen to every new tale that furnishes evidence of inheritance of acquired characters and to the human longing "to pass on to our offspring the fruits of our bodily gains and mental accumulations." But, he significantly remarks, "In our

hope for the best we forget that we are invoking a principle that also calls for the inheritance of the worst." The final chapter, on human inheritance, is of special interest to medical men, for it discusses the genetics of physical defects, colour-blindness, night-blindness, haemophilia, and the four blood groups, by which the selection of donors in blood transfusion is determined. The inheritance of mental traits, insanity, and superiority or inferiority in racial and social groups is also examined in this chapter. The author's conclusion is that the geneticist finds it impossible to discover within each human social group the genetic basis of behaviour with any certainty. Differences, he thinks, are obviously connected, not only with material advantages and disadvantages resulting from location, climate, soil, and mineral wealth, but also with traditions, customs, religions, taboos, conventions, and prejudices. Superiority or inferiority is not a matter of inherited biological characters, but is due to conditions that have their roots in the past, and is acquired by each new generation as a result of imitation and training. He is inclined, however, to think that there are considerable differences in man that are probably strictly genetic, although he insists that at present there is no real scientific evidence of this of the kind with which geneticists are familiar in other animals and in plants.

The impression obtained from the book is that the author, while rejecting the old theories of evolution, adopts an attitude towards genetic inheritance of mental qualities and defects that is agnostic. As a whole, it is full of suggestive thought and scientific possibilities. A drawback to any reader who is not a trained biologist is the difficulty of following some of the charts and illustrations, several of which are photographic reproductions much reduced in size and with inadequate explanations, either in the text or in the legend, of conventional signs and letterings.

POST-MORTEM APPEARANCES.

Dr. JOAN M. ROSS, assistant pathologist to St. Mary's Hospital, has provided a useful handbook on *Post-Mortem Appearances*,² which, from its conveniently small size, might well be called a pocket-book. It is clearly and concisely written, and gives in the appendix tables of the normal weights of the organs in the adult and newborn, and of the eruption of the teeth. There are directions as to the methods of making a necropsy, notes on the preservation of morbid specimens, and descriptions of the appearances in twenty-one kinds of poisoning, including that by veronal.

In any further edition the author might consider the propriety of omitting the word "hyperpiosis" in brackets after arterio-sclerosis, for this implies that they are synonymous. It would be well to maintain the original sense in which the late Sir Clifford Allbutt employed the word—namely, as signifying high arterial blood pressure of obscure origin, not due to, or necessarily associated with, renal disease or arterio-sclerosis, though they may follow in its train. Mitral stenosis is described as being usually in the body of "a female, an adult and possibly old," but this does not quite meet the case, for it is certainly much commoner in children than in old women. As the adjective myeloid is employed to designate one form of leukaemia, lymphoid would be better than lymphatic for the other. These, however, are comparatively minor criticisms, and on the whole the work is distinctly well done, and should be popular with students and useful to the practitioner in making ordinary and medico-legal necropsies.

NOTES ON BOOKS.

THE eighth edition of Dr. T. L. STEDMAN'S *Practical Medical Dictionary*,³ of which the last edition appeared scarcely more than two years ago and was noticed in our issue of February 2nd, 1924 (p. 209), contains many hundred new words, but space has been found for these without

¹ *Evolution and Genetics*. By Thomas Hunt Morgan, Professor of Experimental Zoology in Columbia University. Princeton: Princeton University Press; London: H. Milford, Oxford University Press. 1925. (Demy 8vo, pp. ix + 211; 77 figures. 9s. net.)

² *Post-Mortem Appearances*. By Joan M. Ross, M.B., B.S.Lond., M.R.C.S., L.R.C.P. With a preface by E. H. Kettle, M.D., Oxford Medical Publications. London: Humphrey Milford, Oxford University Press. 1925. (Crown 8vo, pp. viii + 236. 7s. 6d. net.)

³ *A Practical Medical Dictionary*. By Thomas Lathrop Stedman, A.M., M.D. Eighth revised edition. London: Baillière, Tindall and Cox. 1925. (6½ x 9½, pp. xii + 1146; over 400 figures, 15 plates. 35s. net.)

appreciably increasing the size of the book. The number of pages, in fact, is only two more than that of the 1923 edition. This feat has been accomplished by omitting the entries regarding the mineral springs of America and Europe, a subject (as the editor observes in his preface) that properly belongs to special treatises or encyclopaedias rather than to a defining dictionary. As in the last edition, the full-page illustrations have been gathered together at the end of the volume, which on the whole is an advantage. A large proportion of the new terms relate to dentistry, so that "Stedman's" is now in effect a medical and dental dictionary. The work in its revised form maintains the high standard that we have learnt to expect from American medical dictionaries. The spelling, of course, follows throughout American usage, and therefore, to take one instance only, English readers will not find words like "oesophagoplasty" among those beginning with "oe." These little inconveniences must, however, be put up with until such time as a first-rate medical dictionary is produced in this country.

The *Minutes of the General Medical Council and of its Various Committees*¹⁰ for the year 1925 have been published in a bound volume with fifteen appendixes. A detailed report is given of the two sessions of the General Medical Council, together with those of the English, Scottish, and Irish Branch Councils. The presidential addresses of Sir Donald MacAlister at each of these sessions, which were published in our columns when delivered; are also printed here. Copies of the correspondence with licensing bodies as to their new Regulations are included. The *General Index* to the *Minutes* of the General Medical Council and of its Executive and Dental Committees, and of its three Branch Councils, from 1903 to 1925, has also been published. It relates to volumes xl to lxii of the *Minutes*. The plan of previous indexes has been closely followed and each subject is fully indexed, the references being arranged chronologically; in many cases special subheadings have been inserted. This *Index*, revised annually so as to include the last year's items, forms a useful key to the proceedings of the General Medical Council and of its committees.

Dr. R. MOURGUE of Nîmes has prepared a French edition of Professor MONRAD-KROHN's clinical handbook¹¹ on the examination of the nervous system, the translation of which into English has already reached its second edition. The French edition has also been revised and augmented by the author, and a preface has been written by Dr. Souques. The book is very complete, is of a size convenient for use at the bedside, and should prove of special value to hospital residents, clinical assistants, and others who wish to educate themselves in a sound routine in the investigation of cases of nervous disease. No method of importance is omitted, and considerable attention is given to the systematic examination of the mental faculties—a factor of importance often inadequately dealt with in books of this kind. In addition to the chapters on the cranial nerves, motor and sensory systems, cutaneous and tendon reflexes, descriptions are given of the special investigation of cerebellar function, defence reflexes, electrical reactions, cerebro-spinal fluid, Binet-Simon tests, vestibular reactions, and so on. The descriptions throughout are clear and succinct, and the information thoroughly up to date.

The second volume of the second edition of the system of internal medicine,¹² edited by Professors G. VON BERGMANN and R. STAHELIN, is devoted, like its predecessor (see JOURNAL, April 18th, 1925, p. 746), to infectious diseases. In addition to the commoner infectious disorders not discussed in the first volume, such as erysipelas, acute articular rheumatism, septic diseases, and enteric, the present volume contains an account of leprosy, plague, malaria, blackwater fever, sleeping sickness, beri-beri, and diseases common to man and animals, such as actinomycosis, glanders, foot-and-mouth disease, trichinosis, anthrax, and rabies. A supplement to the section on the acute exanthemata contains chapters on exanthema subitum by Dr. E. Glanzmann of Berne, and alastrim and abnormally mild epidemics of small-pox by Dr. Rudolf Massini of Berlin. Some of the articles in the previous edition have been revised either by the original writers, such as that on enteric by Dr. Schottmüller, or by new hands, such as the articles on erysipelas and acute articular rheumatism by Dr. Carl Hegler; other articles,

again, such as those on septic diseases by Drs. Schottmüller and Bengold and on plague by Dr. Rodenhuis, which had formerly been written by Professor Jochmann, are entirely new. Many fresh illustrations, including several in colour, have been added.

To those whose knowledge of the Hebrides is of the desolating and desultory variety, gained as soaked and soured tourists, it is hard to explain the mysterious affection of the islanders for their inhospitable soil. Can the islanders explain it themselves? They leave their homeland to thrive elsewhere, or stay at home to live what is (outside the towns) a hand-to-mouth existence at best. They refuse the dictation of the doubtless well meaning Sassenach millionaire; a Highlander cannot live by high wages alone, and between his ideas and those of the philanthropic plutocrat a wide and impassable gulf is fixed. *Behold the Hebrides*¹³ tells us how if it cannot tell us why; for the author is himself an islander with the Gaelic blood and tongue. So here we have vivid pen-pictures of hill and sea and rain and mist, with the telling of tales about the mighty and high-handed heroes of the past, romantic heroes like Ruairi an Tartair, "the noisy and turbulent Roderic" who dwelt in Kisimul Castle and domineered over sea and land. No weather held him back; no mercy had he for friend or foe; merchant galleys existed only for the filling of his cellars with casks of the rarest vintage from Spain and France, or to supply gold—gold, no less!—for the shoes of his three pairs of black steeds. A great man, in truth, and not without due appreciation of his own merits. For, after he had feasted, his bugler sounded a call from the Kisimul tower to announce to all lesser folk that since Ruairi the great chief had dined, "all kings and princes of the earth were now permitted to do likewise." And later, captured and tried in Edinburgh, he defiantly explained his acts of piracy on the Queen of England's merchantmen as being his only means of avenging the cruelty which Mary, mother of the king, had suffered at the hands of her royal sister. His plea saved him his life but not his lands and heritages, and

"In Barra Ruairi
Was a daring chief no more."

Here, too, our author gives us the strange tale of the Fifo Adventurers and their ill fated attempt to settle amongst a warlike race (although the Southrons dubbed them "bludie and wicket Hielandmen"), and the prolonged and cruel struggle that ensued. Of Dunvegan and the Faery Flag, of the tragic cave at Eigg where the MacLeods suffocated two hundred MacDonalds by a fire of peat and sun-dried bracken kindled at its mouth and kept fiercely burning until all within had succumbed, of many more feats of the dirk and claymore we have the vivid telling. It is a book every expatriated Highlander will love to have in his hands, while the Southron is thoughtfully provided with the crutch of a glossary to help him round the more difficult corners. It is to be hoped that at no late date Mr. MACGREGOR will give us another Hebridean volume.

Whoever is interested in the subject of sugar ought to read Mr. GEOFFREY FAIRRIE's book.¹⁴ It is, we believe, the only thing of its kind relating to sugar; it combines a popular account of all the phases of its production, with a technical description of the processes used in its manufacture and preparation for the table. Lest anyone think that such a combination of purposes must result in a dull volume, we hasten to assure him that the book is full of life, for the writer knows his subject (he is a manufacturer connected with a large sugar refinery), and he has an entertaining way of telling his story. How many amateur philologists knew that the word "sugar" is derived from Sanskrit *caraka*, meaning grains of sand? We admire the facility with which the writer has interwoven his digressions; these never wander far without returning directly to the subject; they always contain engaging information and fit the theme aptly. In a brief allusion to Demerara crystals it is explained that owing to a less complete process of refinement than that used for white crystals some of the natural plant juice remains adherent to the crystals, and that such crystals (technically known as direct consumption raw sugars) are sometimes prescribed by physicians for infants on account of the laxative action of the adherent juice. The description of mechanical inventions is quite exhaustive both as to historical development and present uses. Incidentally it is remarked that Bessemer, famous in the steel industry, was the holder of numerous patents connected with sugar production, and that he promoted a company which erected a new sugar refinery

on the Thames. This refinery, however, was closed after two or three years, the capabilities of the great man in relation to steel not being adaptable to the demands of the sugar industry. This book may be recommended to all who have any interest in the subject—to the grower for the discussion on conditions of production; to the manufacturer for the description of mechanical plant; to the merchant for the statistical account of crops, prices, duties, and so on; and to the general reader for much interesting information.

PREPARATIONS AND APPLIANCES.

A Breaker for Suture Tubes.

Mr. H. G. BARNHAM BLACKMAN (Norwich) writes: I have designed the tube breaker, illustrated herewith, to obviate any risk of cutting the gloves or even the fingers in the act of breaking the glass tubes in which catgut is supplied. Occasionally the tubes are very difficult to snap, and in using much force the likelihood of broken glass perforating the gauze and puncturing the gloves is very great. The breaker consists of two portions of tubing separated by a long hinge which can be opened in either direction.

At one end there is a cap which fits on the tube by means of a bayonet joint. This cap can be quickly removed, the tube of catgut slipped in, and the cap replaced. The glass tube can then be snapped quickly and neatly by opening the hinge in either direction. The catgut is easily withdrawn by means of a pair of dissecting forceps, and by opening the hinge to its full extent the broken tube can be shaken out. If a tube of catgut is unusually short, a small portion of sterile cotton wool can be pushed down to the far end of the instrument so as to bring the file mark on the tube near the centre of the gap. To remove the wool later is quite simple, as the cap at the far end unscrews. The appliance is made by Messrs. Down Bros., Ltd., 21 and 23, St. Thomas's Street, London, S.E.1.

Hyperol.

Hyperol (solid hydrogen peroxide) is a preparation in tablet form of a compound of hydrogen peroxide and urea. It is made by Messrs. F. W. Berk and Co., Ltd. (106, Fenchurch Street, London, E.C.5). A tablet of 0.55 gram (8½ grains) yields 55 c.c.m. of oxygen, and this corresponds to a content of 30 per cent. of hydrogen peroxide in the tablet. A tablet dissolved in 5 c.c.m. of water will therefore form a 10-volume solution of hydrogen peroxide. These tablets are a very convenient form for transport of hydrogen peroxide; by their use fresh solutions of hydrogen peroxide can be obtained with a minimum of trouble.

ROYAL MEDICAL BENEVOLENT FUND.

At the last meeting of the Committee fifty-seven cases were considered and £577 voted to forty-four applicants. The following are notes on some of the cases relieved.

Widow, aged 50, of M.R.C.S. who died last year. When the late husband's estate is settled up the income will be about £200 a year for herself and three children, two boys 13 and 8 years and a girl of 11. The Committee made a small grant to render the case eligible for the Guild's assistance with education.

Widow, aged 37, of M.B.Manch. (1908) who died last April. Left with three children aged 10, 5, and 2, without any income, and too ill at present to do anything towards maintenance of self or children. The applicant asks for assistance for education. The Committee made a small grant so that the Guild can deal with the case.

L.A.H.Dubl. (1907), aged 47, married, one son aged 14. Six years' war service. Sold practice before joining up. Has repeated attacks of malaria. Now unable to find employment. Medical work for the last twelve months brought in £165. Officers' Association granted £15. Has pawned and sold various articles. Voted £7.

Widow, aged 65, of M.R.C.S.Eng. who died in 1922. Her only income is about £42. Lives in one room at 9s. a week. £5 voted by the Committee and application has been made for a grant from the Masonic Benevolent Fund.

Daughter, aged 70, of M.R.C.S.Eng. who died in 1872. Used to make a living by teaching small children, but had to give up this to look after her mother, who died in 1920. Tries to let a portion of a house, but is at present without a tenant. She received £25 from letting and a brother allowed her £27. She has had the old age pension since August last year. Rent and rates £58. Voted £9 in twelve monthly instalments.

Widow, aged 37, of L.R.C.P.Ed. (1917) who died last March. The house and shop where she carries on a small business has been sold and she will have to vacate the premises in a few months. Has one boy, aged 12, for whom she asks educational assistance. The Committee made a small grant and handed the case over to the Guild to deal with.

Subscriptions may be sent to the Honorary Treasurer, Sir Charters Symonds, at 11, Chandos Street, Cavendish Square, London, W.1.

The Royal Medical Benevolent Fund Guild still receives many applications for clothing, especially for coats and skirts for ladies and girls holding secretarial posts, and suits for working boys. The Guild appeals for second-hand clothes and household articles. The gifts should be sent to the Secretary of the Guild, 58, Great Marlborough Street, W.1.

PRINCIPLES OF TREATMENT IN DISEASES OF THE NERVOUS SYSTEM.

FIRST LETTSOMIAN LECTURE BY DR. E. FARQUHAR BUZZARD.

At the Medical Society of London on February 15th Dr. E. FARQUHAR BUZZARD delivered the first of three Lettsomian lectures on the general subject of "Principles of treatment in relation to diseases of the nervous system."

Dr. Buzzard opened with a reference to John Coakley Lettsom, and quoted a passage from an address on Lettsom by Sir StClair Thomson indicating the prevalence of quackery in the time of the eighteenth century physician. Dr. Buzzard remarked that notwithstanding the advances made since then in the science of medicine the rivalry of quackery remained undiminished, if it had not increased. How was it that orthodox methods of treatment, which had steadily gained in range and efficacy, had hardly done more than hold their own? It was easy to answer the question by asserting that there was no limit to the ignorance and credulity of the public in medical matters. But could medical men boast that they had used their position and authority to the best advantage in gaining the confidence of their lay brethren? There might be two opinions as to the possibility of educating the public to the requisite state of medical knowledge. In other matters, less intricate, the public was content to follow the experts it employed; and it was hardly likely that in medicine, which required a long training, not only in its own principles, but in preliminary sciences, the layman could ever aspire legitimately to a position from which he could speak with competence on medical subjects. This consideration, while it would not stifle the incompetent critic, might lead some medical men to question how far attempts to educate the public in medical lore should be promoted. But if it was impossible to educate the public sufficiently in medicine to enable them to realize the advantages of treatment governed by scientific knowledge over that which depended on ignorance and credulity for its acceptance, some other method must be found for establishing the position and supremacy of the qualified profession in relation to its unqualified rivals. Some means must be found whereby the confidence of the public in medical practice could be won and preserved.

The Meaning and Importance of Diagnosis.

How was all this related to the topic of these lectures? In the first place, it was essential, in order to apply principles of treatment with success in practice, to hold the confidence of those submitted to such treatment. In the second place, it seemed necessary to review critically the methods of treatment in general use, with special reference to their effect on the confidence of the patient and his respect for his medical man. At the present moment there was a lack of mutual understanding between the profession and the public. An atmosphere charged with mistrust was not congenial to therapeutic work, and if he could contribute any suggestion for the creation of better climatic conditions he would risk an occasional burst of thunder.

The first step towards the creation of a better atmosphere would be to have it announced abroad that physicians—he could not speak for surgeons—made no pretence of curing disease, and, although they claimed some understanding of morbid processes and disorders of function, they were in a position to act only as Nature's allies and agents. Let the claim to cure disease be left to the unqualified. The first principle of treatment was a preceding diagnosis. Diagnosis was, or should be, much more than a label. It should indicate the pathology and natural history of the morbid process. The doctor's responsibility did not end with labelling a patient's disorder and prescribing treatment. He should be in a position to describe in general terms the nature of the malady and the course it was likely to take, as well as the objective and probable effects of the measures he recommended. It was true that the patient was content with a name and insisted on having some form of treatment.

Here osteopathy had an advantage: the osteopath had only one diagnosis (a bone out of place) and one treatment (replacement). The simplicity of this appealed to the lay mind. But was it not possible that if medical men one and all gave more frank advice to their patients, even though they ran the risk of losing a few of them, the time would come when the public would listen to their words of wisdom? Medical men all denounced quacks, some would legislate against them, but far too many imitated them. Only by raising the standard of practice in proportion to knowledge, and by living up to ideals foreign to their competitors, could they hope to win the public respect which was due to a qualified profession.

Lesions of the Upper Motor Neurone.

Dr. Buzzard then turned to a consideration of the principles which should guide treatment in lesions of the upper motor neurone. He instanced a patient suffering from right hemiplegia resulting from a vascular lesion in the neighbourhood of the left internal capsule, and described the instructions which should be given to the nurse with regard to the movement of the paralysed limbs. In 75 per cent. of such cases massage and electricity were likely to be ordered, and the patient would be allowed tacitly to understand that these were the agents responsible for his recovery. It might be that simple passive movements were desirable for preventing complications, and that a little rubbing would promote circulation in limbs apt to become cold and stiff. But if the current wasted in a year on the limbs of hemiplegic patients could be stored in accumulators it would go far to assist the Government scheme of electric supply! Electricity in some departments of medicine was as unjustifiable and useless as osteopathy, chiropractic, and the like.

He described the simple and rational explanation which he would give to the patient of his disability. The patient should be told that much depended on his own efforts. He must not expect any treatment applied to the limbs in the way of rubbing or manipulations to restore the power of movement. The object of the masseur was to keep the joints in good condition until such time as the patient could make use of them. The patient should be told to devote a few minutes several times a day to systematic attempts at movement, studying the movements on the sound side and endeavouring to repeat them on the other. The masseur of the present day was, of course, often intelligent enough to encourage his patient to carry out movements against resistance, and so to enlist his interest in his paralysed limbs, which was the first therapeutic requirement; but in ninety-nine cases out of a hundred the patient was convinced that it was what the masseur did to him and not what he did himself that was responsible for his gradual recovery. What did it matter as long as the patient improved? It mattered a great deal, both from the point of view of the patient's pocket and the reputation of the profession.

Lesions of the Lower Motor Neurone.

Dr. Buzzard next touched on lesions of the lower motor neurone, and instanced a case of acute poliomyelitis. What could be done with muscles showing no sign of life except their ability to respond to the make and break of a galvanic current? No method was known of restoring function to the neurones temporarily crippled. One could only keep the paralysed parts in so healthy a condition that any restoration of function might find the muscles, tendons, and joints fit to take their place once more. Simple passive movements were to be recommended, and the nutrition of the muscles must be maintained by keeping them warm, and by rubbing, and their contractility might perhaps be promoted by applying a certain amount of electrical stimulation. The length of time for which these measures should be pursued would vary. In acute poliomyelitis it was customary to teach that treatment should continue for twelve or eighteen months after the acute illness. But if the treatment had been efficient from the onset, muscles which showed no return of function at the end of four or six months would not develop a sufficient amount of power to be of any practical use, however long the massage or electrical treatment was continued. A general recognition of the principles

governing treatment would save muscular energy, electrical current, time, and money. Further treatment must depend on the nature of the disability and the orthopaedic measures which could be devised to reduce it to the minimum.

The Psychological Adjustment of the Patient.

In cases in which there was degeneration of the motor neurone he summarized the advice and assurances which might be given to the patient, a simple and true explanation of his condition, the fact that there was no reliable remedy, the necessity for avoiding needless muscular exertion, the futility of muscular exercise in the hope of restoring power, and of electricity and the injection of drugs like strychnine, which could do no good and might possibly do harm. Gentle massage might be helpful in maintaining nutrition of what muscular tissue was left, but it should not be regarded as remedial. The patient should be told that he had nothing to fear with regard to pain, and that although the condition was not free from danger those similarly afflicted had lived for many years, and their lives had not been shortened.

This gave the patient the opportunity of making his psychological adjustments to whatever fate might have in store for him, and enabled him to avoid the pursuit of many false remedies, the raising of false hopes, and cruel disillusionment. Medical men were responsible for the psychological as well as the physical condition of their patients, even when there was organic disease to be treated. By such means the standard would be raised above that of quackery, and the public would be left in no doubt as to where to place its faith.

Nova et Vetera.

A VENERABLE MAN OF SCIENCE.

PROFESSOR NAUNYN'S MEMOIRS.

THE "Reminiscences" of Professor Naunyn,¹ whose death has removed from among us one of the most venerable figures in the world of medical science, were published but a few months ago, and cover, therefore, practically the whole span of his long life of eighty-six years. The book is one which, we have little doubt, will be as durable as his scientific work, and no one who is interested in the history of medicine during the latter half of the nineteenth century can afford to neglect it. He had, it is true, and as he himself has stated, no very startling incidents to relate, such as might be found enlivening the memoirs of a royal or imperial aide-de-camp; but he was himself a participator and contributor in the great forward movement of his time, and could write with knowledge of the men and events concerned in it. And this he has done evidently with that studied regard for accuracy which characterizes his own scientific work and that of his race, and which renders the fund of information contained in his book of sterling worth.

Perhaps the most important part of the memoirs is to be found in the vivid character sketches that are thickly scattered through the volume from beginning to end. By means of these we seem to gain an intimate acquaintance with the personalities of many men whose names have hitherto tended to stand for us rather in the nature of algebraical symbols of scientific facts. The fascination of depicting character, which Professor Naunyn evidently felt, apparently arose from his habit of searching for evidences of a capacity for friendship (not mere friendliness, he was careful to explain) in his acquaintances; "a man and a friend" might well have been his motto, and in these observations of his the good qualities of a man naturally came uppermost, and whatever might be his foibles he always had an honest chronicler in Professor Naunyn. Not that foibles were overlooked, though they were often mentioned to be palliated. Thus, in a generous panegyric on his co-worker Mikulicz, for whom he had an unbounded admiration, an inability to say "No" is

¹ *Erinnerungen Gedanken und Meinungen des Dr. B. Naunyn, Emeritierter Professor der innern Klinik Universität, Strassburg. München: J. F. Bergmann. 1925. (Demy 8vo, pp. 571; 1 portrait.)*

referred to, a weakness which gained him the reputation of breaking his promises, and was detrimental to the full recognition of his outstanding qualities. Naunyn repudiates the fact as merely marking the constitutional difference between a light-hearted Viennese and a cool, adroit Prussian or shrewd Hessian, for instance. These character sketches sometimes give us mere passing glimpses, as in the case of the venerable Professor von Baer, who comes upon the stage for a few moments suffering from a supposed incipient hemiplegia, which is forthwith cured by the removal of a hypertrophied toe-nail, which had been overlooked. In other instances, as in the account of Frerichs, the details are sufficiently full to give a valuable picture of the man and his work.

It was under Frerichs at the Charité in Berlin that Naunyn acquired that interest in the pathology of metabolism which bound him to the study of the liver, pancreas, and diabetes for the rest of his career. It was an interesting period in the history of medicine, for at that time German clinicians were beginning to install laboratories in which the problems of clinical medicine were studied by the experimental method and with all the technical refinements afforded by the natural sciences. It was a movement of far-reaching importance, for in these German laboratories experimental pathology took its birth, and attracted scientists from all parts of the civilized world. When, later, Naunyn was called to the chair of clinical medicine in Strassburg his interest in clinical pathology naturally incited him to improve the clinical side of the institute there, which was in a backward condition. Pathological anatomy appears to have been in the ascendant at the time, under the influence of the vigorous personality of Professor von Recklinghausen. Hence arose something in the nature of a stone of stumbling and rock of offence, which it became Naunyn's business to surmount. Von Recklinghausen seems to have dominated the faculty. We are told that in committee he always spoke first and often, and always at great length, explaining in the first instance what he did not want, and often leaving it doubtful, both to his hearers and to himself, what he really desired. Such dominating personalities are not unknown among idealist members of committees in our own country, but von Recklinghausen appears to have been abnormally tenacious of principle. In urging the claims of clinical pathology Naunyn had the temerity to suggest that there should be some give-and-take in the matter—compromise, in short. "What!" exclaimed von Recklinghausen, "I to yield to a demand that I consider unjustified! You are asking me to make a sacrifice intellectus!" Naunyn had his way, and to this little *rencontre* we are indebted for a pleasant glimpse of the famous pathological anatomist, for whom Naunyn naturally had the greatest admiration.

If these character sketches constitute the most interesting part of the *Reminiscences* their most attractive feature is certainly to be found in the delineation of the author himself. With a minuteness of detail resembling the work of the old Dutch painters he has unconsciously drawn a portrait which it is pleasant to contemplate in its restrained and quiet colouring and homely circumstance. We are told of the old home in Berlin, and its inmates; of Burgomaster Naunyn, his father, and his troubles with the revolutionaries of '48; of his schoolmasters, and especially of Jungk, whom he credits with implanting in him his lasting distaste for superficiality of thought and expression; of his student life in Berlin, where he came in contact with Reichert, Frerichs, Traube, Lieberkühn, Langenbeck, Du Bois-Reymond, Virchow, and others, the representatives of the new school of German medical science; of the "Dissertation on the development of the echinococcus," the product of his earliest research. From 1869 to 1871 he held the chair of clinical medicine in Dorpat; and that in Berne from 1871 to 1872, passing in the latter year to Königsberg, where he remained for sixteen years. He then succeeded Kussmaul in Strassburg, finally retiring from professorial work in 1904, and taking up his residence in Baden-Baden, where he passed the remaining years of his life. He did not retire into idleness, however; his two journals, the *Archiv für experimentelle Pathologie* and the *Mitteilungen aus den Grenzgebieten*, as well as

other literary work, engaged his thoughts, and he was also occupied on the *Reminiscences*.

During the war, notwithstanding his great age—for he was nearly 80—he was unwilling to remain inactive, and for a time occupied a post in a military hospital in Baden-Baden; and there the old passion for pathological research revived in him, and he recommenced the study of cholelithiasis, which engaged his interest almost to the end of his life. "Thus," he writes, "the activity to which I devoted my life has, in old age, been my own familiar friend, and has helped me through these troublous times, in so far as that was possible."

In the memoirs of a man of so sympathetic a nature as Naunyn it is natural to search for those more intimate traits which form, so to speak, the mainspring of individuality. As to his religious opinions, he gives us very little information; he tells us, not without a touch of humour, that if, as he had been told, a man's work was his religion, then he reckoned himself to be a very pious man. As to his love affair, for the fragmentary but charming hints of his courtship of his pretty cousin Anna the reader must turn to the book itself. Of his conception of friendship as one of the main foundations of the worth of life we have already made mention. Of his quiet sense of humour the memoirs contain many instances, although one will, perhaps, appeal more especially to the readers of this journal. "I was beginning to become famous," he writes; "foreign countries began to notice me—and England first of all. The first invitation came in 1874 from the British Medical Association, and ran as follows: 'Lodging with breakfast, but without dinner!' This conscientious recognition of my qualification as a guest pleased me, as I was a great friend of the English at that time."

The central point of the *Reminiscences*, however, remains to be mentioned—the high-light of the whole picture as it were. In one passage Naunyn dimly hints that his book owed its inception to the single idea that he might enshrine within it the memory of his wife; and assuredly no more noble tribute was ever penned than the description of her virtues with which he has adorned his pages.

HEALTH ORGANIZATION IN LATVIA.

SCARCITY OF DOCTORS.

LAST October (vol. ii, p. 759) some account was given of the reports made to the Health Organization of the League of Nations on medical and public health services in Czechoslovakia and Greater Serbia. There has now come to hand a report on Latvia, one of the Baltic states, which again demonstrates that the Organization arrived at a wise resolution when it determined early in its proceedings to allow a large latitude to the authors of the series of reports on the health organization of countries embraced in the League. The report for Latvia¹ is by Dr. Cazeueneuve of Geneva, who spent some time making inquiries in that country. He states that, in 1923, the population was close on two millions (1,661,187), and that there were 813 doctors, 168 surgeons specially recognized by the Department of Public Health,² 880 midwives, and 538 dental surgeons. This gives one doctor per 2,276 inhabitants, so that rateably to population the medical service should be reasonably sufficient. But the distribution of the 813 is remarkable, for no fewer than 425 are in the capital city Riga, which has a population of 285,000, or at the rate of one per 670 inhabitants. More than half of all the practitioners in Latvia are thus in one town, containing less than a sixth of the population. There are three other towns, with a total population of 143,193, sharing amongst them the services of 123 doctors, one to every 1,163 inhabitants. Excluding these four towns, the country consists of three provinces, with a total population of 1,533,224, and these have among them only 265 doctors. This gives one practitioner to 5,785 inhabitants. But even here the distribution is very unequal—in one

¹ Organization of the Public Health Services in Latvia. By Dr. J. H. Cazeueneuve, Geneva.

² These are probably included in the 813.

province (Vidzeme) the population to each doctor is 3,928, in another (Kudzeme) 5,980, and in the third (Latgale) 8,817. Compared with Riga, Latgale, which has over half a million people, has only one doctor for every thirteen in the equivalent population of the capital city. If the facts were known it would probably be found that within Latgale itself there is irregularity in the areas and populations supposed to be served by the sixty doctors in the province. Dr. Cazeneuve calls attention to the special conditions of life and the way in which the population is distributed in the rural areas. "In Latvia," he says, "the peasants' dwellings are not, as a rule, close together in hamlets and villages, but are scattered over the whole surface of the arable land. The breaking up of the big estates under the new agrarian laws has accentuated this dissemination of dwellings; the holders of the new estates, which run to about 20 hectares, establish their farms on the land they acquire. The difficulties of communication and the great distances to be covered render the exercise of the medical profession in the rural districts particularly arduous."

In such conditions there must be many instances of serious and fatal illness in which regular medical attendance, or perhaps any medical attendance, is unobtainable. At the same time, it is right to point out that the provincial conditions of life described by Dr. Cazeneuve have their redeeming features in respect of health. The peasants' dwellings, scattered as they are, must be singularly free from risks of spread of infectious or contagious disease, acute or chronic, while whatever be the character of the houses themselves, and the habits of the people, their outdoor peasant life will naturally be healthy. In view of these considerations, the death rates, as stated by Dr. Cazeneuve, are of interest. In the year 1923 they were as follows, beginning with the lowest:

				Per 1,000 inhabitants.
Kudzeme (Courland)	12.12
Vidzeme (Livonia)	13.12
Riga	13.72
Zemgale	13.88
Latgale	14.89

Latvia as a whole had a rate of 13.66. Without fuller knowledge than is available, the suggestion is not unreasonable that the excess of the Latgale rate over that of the country as a whole may be largely due to deficiency of medical attendance. The question naturally occurs whether the lack of doctors in the country districts may not, especially as regards women and children, be supplemented by the service of midwives. But the report gives little indication of such relief. Of 813 midwives in Latvia, 336 are in Riga, 150 in other towns, and only 345 in all the rest of the country. How these are distributed throughout the provinces does not appear.

The following table for the year 1923 by Dr. Cazeneuve, relating to the countries bordering on the Baltic, is of interest.

	No. of physicians.	No. of physicians per 10,000 inhabitants.	No. of inhabitants per physician.
Latvia ...	813	4.39	2,276
Lithuania ...	410	1.74	5,741
Esthonia ...	534	4.45	2,247
Finland ...	720	2.22	3,372
Sweden ...	1,771	2.96	4,730
Poland ...	5,192	1.96	5,079
Germany ...	38,186	5.98	1,667

This shows that, taking the countries as a whole, Latvia is very much better off as regards medical supply than most of the others, and it has already been pointed out that in Latvia the distribution, not the number of doctors and midwives, is at fault. It will be seen that Lithuania, Poland, and even Sweden, have not for their populations respectively one-half the doctors of Latvia. Germany, on the other hand, has one doctor to 1,667 inhabitants. (In England, Scotland, and Ireland, in 1923, the proportion

of doctors was even greater than in Germany, the total being 35,447, which, in a population of, say, 45 millions, gives one doctor to about 1,270 inhabitants.)

The conditions in Latgale resemble those in the Highlands and Islands of Scotland before the Medical Service Act. As the bulk of the working class in these regions were not under any "contract of service" but occupied on their own account as crofters and fishermen, etc., the Insurance Act did not apply to them, so that they could not have the services of insurance practitioners as such. At the same time earnings were low, money as a medium of exchange scarce, and direct payment for attendance difficult. Another factor in the case was that the distance from the nearest doctor was often so great as to make reasonable payment not merely difficult but impossible. A committee appointed by Government to inquire into the whole position found that extraordinary hardships were resulting from these conditions, both to the people and to their doctors. On considering the committee's report the Government introduced and passed a measure of relief for the provision of medical and nursing attendance, etc. Distance from the doctor was entirely set aside in considering the amount of the fee to be paid by the patient for the visit. The charge for attendance at ten or twenty miles' distance was to be the same as if the patient lived in the same village with the doctor, and the difference was made up by payment from a fund voted by Parliament for the purpose. Some aid was given also towards the provision, where necessary, of small hospitals and houses for doctors and nurses. That is the meiest outline of the main features of an Act which has practically revolutionized the medical and nursing service in the Highlands and Islands of Scotland.

It seems most unlikely that any such scheme is at present practicable for the provinces of Latvia, having regard to what the report incidentally mentions as to the economic conditions of that country, but some such ideal should be kept in mind when the possibility of its attainment comes within sight. Roads and other means of transit may be worse in Latgale than in the Highlands, and the population may be even more sparse and difficult of access. Dr. Cazeneuve's report tells about the devastated area of Latvia, which had previously been one of the best cultivated and most prosperous in the country. There were destroyed 25,000 farms, over 100,000 buildings, 170,000 cattle, 28,000 carts, 20,000 ploughs, and 12,000 agricultural machines. More than 300,000 inhabitants, including 92,000 children, were left homeless, without clothing or means of support. All this was a terrible handicap to the new Government, but with charitable aid, including that given by the American Red Cross and Child Welfare Organization, the situation has been faced and relief and reconstruction begun.

A new health scheme had to be built up on the ruins of the Russian system. A campaign against typhus was a measure of the utmost urgency, involving hospital re-organization and equipment, along with the re-establishment of notification, isolation, and disinfection. At the same time improvement in water supply and sewerage had to be undertaken. The progress already made is wonderful. A new university, which had 854 students in 1923, was founded at Riga for medical instruction, whilst a health commission and health boards, analytical and vaccine laboratories, and welfare associations have been established, central and local health services, including a coastal service and quarantine station, have been organized, as well as workmen's insurance against sickness and accident, and sanitary inspection of factories and workshops.

But this story is too long already, and cannot be extended to give even a synopsis of the account of the stage now reached in the establishment or re-establishment of modern health services in the sorely stricken nation of Latvia. Dr. Cazeneuve's account is full of interest from beginning to end. As regards health legislation, he shows how far the old Russian laws have been adapted to the new conditions, and he reviews the present administration in respect both of official and philanthropic activities, central and local.

British Medical Journal.

SATURDAY, FEBRUARY 20TH, 1926.

IMMUNITY REACTIONS TO PNEUMOCOCCI.

An explanation for the dramatic crisis and sudden fall of temperature which occurs in favourable cases of pneumonia is provided by experimental work which Dr. R. R. Armstrong has recently completed (*Proc. Roy. Soc., B.*, vol. 98, 1925).¹ He devised a method which enabled him to measure accurately the protective power of serum prepared by immunizing rabbits with pneumococcal vaccine against measured doses of living pneumococcus cultures, using mice as test objects. When rabbits were inoculated with pneumococcal vaccine immunity developed in a remarkable and characteristic manner. An inductive phase, lasting three to five days, was followed by an outpouring of protective antibodies into the serum at a rapidly increasing rate corresponding to a geometrical progression, a maximum concentration of protective substances being reached on the eighth day after inoculation. This sudden liberation of antibodies is shown very clearly by logarithmic curves, which have the following characteristics. The first phase, described as the inductive period, is occupied by a neutralization of any natural non-specific immunity present. This is followed by a phase of rapidly developing and increasing immunity, and this again by a phase during which the immunity rises regularly but more slowly to a maximum. Finally follows a phase of constant high immunity, which may be regarded as the period during which, probably, the serum is saturated with immunizing substances. We should look on the crisis in a case of pneumonia as the signal of the sudden and prolific liberation of antibodies, provoked by the gradual growth of the pneumococci in the lungs.

Many of the facts that Dr. Armstrong has elicited from his experimental work may have an important bearing on the question of protective immunization against pneumonia. Thus he found that, provided very large or very small doses of vaccine were avoided, an exact correlation existed between the quantity of pneumococcus vaccine inoculated and the immunity response. The smaller the vaccine dose, the less complete and shorter was the phase of neutralization and induction. The smaller the dose the earlier did immunity appear and the sooner was the maximum immunity attained. He found also that the smaller the dose the shorter was the period during which active immunity persisted. In short, the maximum immunity attained was proportional to the size of the dose of vaccine, provided, of course, that this was not too large.

Dr. Armstrong has also compared the antigenic properties of sensitized and raw pneumococcal vaccines. The pneumococcus, like other bacteria, combines proportionally with its homologous protective antibodies to form a "sensitized" vaccine.

On inoculation a sensitized vaccine liberates the greater part of its charge of antibodies, rapidly conferring a slight degree of immunity, and afterwards excites an active immunity in a manner comparable to that of a raw vaccine. Sensitization, however, leads to a reduction in the intensity and to delay in the immunity response, compared with that following an equal dose of raw vaccine. These effects were imitated by separate administration of immunizing serum both before and after inoculation with vaccine.

The quantitative methods of study employed by Dr. Armstrong have yielded information which forms an important contribution to our knowledge of the mechanism of immunity towards pneumococcal infections. Moreover, they promise ways of gaining a clearer insight into some of the problems connected with preventive inoculation against pneumonia in man.

UNQUALIFIED MEDICAL PRACTICE.

THE parliamentary debate (reported in our last issue at page 306) on Dr. Graham Little's motion for an inquiry into irregular medical practice may have served a useful purpose; for, although the motion and Mr. Atkinson's amendment on behalf of osteopaths were both talked out, the Minister of Health took the opportunity of expressing his views, and this has done something to clear the air. The main point in Mr. Chamberlain's speech was that he could support neither the legal recognition of osteopaths and other irregular practitioners, nor prohibition of practice by them. A good many years before the Medical Act of 1858 was passed proposals to prohibit the practice of medicine by unqualified persons were made by the medical profession during discussions and interviews with Ministers. The then Home Secretary, Sir George Graham, was very emphatic in his refusal, and as he clearly had the support of Parliament those who were engaged in promoting the Act had to realize that, were the proposal persisted in, legislation which was greatly needed for other purposes would not be obtained. There is, therefore, nothing new in Mr. Chamberlain's attitude; he is merely continuing the policy of his predecessors. The new point is that he has so emphatically rejected the proposal to afford some sort of legal recognition to osteopaths and other irregular practitioners. This is, of course, satisfactory to those who desire protection for the public, but cannot be expected to satisfy the osteopaths and other organized irregular practitioners who are asking for statutory recognition, and it is not to be supposed that the present agitation will immediately subside. Incidentally, however, the debate also gave an opportunity for the raising of a different, though not wholly unrelated, issue—the disciplinary powers and decisions of the General Medical Council. Dr. Little did not himself branch off into that sidepath during the debate on February 9th, though he has written much good sense lately about the General Medical Council and the Asham case, both in the correspondence columns of the *Times* and in an article in this month's issue of the *Nineteenth Century*.

The two subjects—irregular practice and the General Medical Council—have, however, become so mixed up in the lay press, in Parliament, and elsewhere, that it is difficult to consider one at the present time without touching upon the other. The General Medical Council has, of course, no powers over irregular practice. Its only concern with it is to warn registered practitioners against assisting or covering the medical practice of unregistered persons (especially in such

¹ Dr. Armstrong's experiments were carried out in the research laboratory of St. Bartholomew's Hospital, with the assistance of a grant from the Medical Research Council. Acknowledgements are expressed to Sir Frederick Andrewes and Dr. M. H. Gordon. His interest in the serological characters of pneumococci appears to have begun when he was research scholar of the British Medical Association (see *BRITISH MEDICAL JOURNAL*, 1914, vol. ii, SUPPLEMENT, p. 57, and *BRITISH MEDICAL JOURNAL*, 1921, vol. i, p. 259).

a way as to mislead the public as to the status and qualifications of such persons), and to punish those who do so by removal from the *Medical Register*, or by suspension of judgement to give the offender an opportunity of mending his ways. The artificial agitation against the penal procedure of the Council has, among other things, focused attention upon two matters—the first relating to the Council's constitution, and the second to its jurisdiction. By statute the Council need not be a wholly medical body, though in fact it has always hitherto been so. We see no particular advantage in including a lay element in a professional body concerned with education and registration, and some strong objections may be taken to this course; but if the Privy Council or the universities choose to nominate laymen they would be acting within their powers. It is quite possible that a brief experience by laymen sitting within the Council might dispel once and for all some astonishing misconceptions about the procedure and capabilities of that body. In regard to the claim that there should be a right of appeal from the disciplinary decisions of the Council, there are obvious disadvantages in allowing the man who wants publicity at any price to get the double advertisement of a hearing by the General Medical Council followed by an appeal to the High Court. A certain type of man, who now hesitates to trail his coat at the Council, might well be encouraged to do so by the opportunity for limelight displays which further proceedings in the courts would afford him. It is apt to be forgotten that at any of the Council's six-monthly sessions a man who feels himself aggrieved by an adverse decision may plead for reconsideration. As for the case of Dr. Axham, our feeling, since he quitted his association with an unqualified person and is not in a position to resume such an association, is that clemency would not come amiss. This was a matter in the first instance for the Colleges whose diplomas he had forfeited after the General Medical Council, having heard the charge brought against him by an outside body, had struck his name off the *Medical Register*. These Colleges could scarcely be expected to restore his diplomas until (as has now happened) he or his friends applied to them; nor has it been within the power of the Council itself to take any action until this was done.

From this digression we return to the question of unqualified practice in medicine and surgery by osteopaths, chiropractors, and other irregular practitioners. Dr. Graham Little's motion in the House of Commons called for an authoritative inquiry, with the object of making recommendations to Parliament for dealing with the whole position. Two of the many points he made may be recalled here. Early in his speech he said that the keynote of unqualified practice was the secrecy of the methods employed and the absence of opportunities for clinical study; and at the close he spoke of the terrible neglect of the poor through unqualified medical treatment, referring in particular to the dispensing chemist, the optician who pretended to be an ophthalmologist, and the quack dentist who fitted new plates upon septic stumps. Another medical M.P., Dr. Shiels, while doubtful of the need for an inquiry at the present time, agreed that some observation ought to be kept on unqualified practice. He rejected altogether the counter-proposal that a general diploma should be recognized for osteopaths, on the ground that no one could safely be given any sort of licence to practise without some proper guarantee of a definite minimum of fundamental scientific and medical knowledge. The Minister of Health, after some sound

remarks on the dangers of irregular practice, made short work of the claim, put forward by Mr. Atkinson and other parliamentary friends of osteopathy, for the recognition and registration of manipulative practitioners "having approved qualifications." Such recognition and registration, he said, would be taken by the public as a guarantee, though it would in fact be nothing of the kind. How, he asked, could a nation lay down rules for the testing of skill? The State would have to fall back on diplomas given by American colleges—diplomas into the value of which it could not examine, and colleges over whose qualifications it had no control; that was not practicable. On the other hand, he knew nothing to prevent the osteopaths setting up their own colleges and giving their own diplomas. They would then be forced to do what had been done in America: their curriculum would gradually approach to the normal. He thought the House would therefore do best to leave things to develop in their own normal fashion. Thus Mr. Chamberlain came down strongly, and with the weight of a Cabinet Minister speaking in the House, against any idea of an official register for osteopaths. That is all to the public good.

While the confusion of the public mind about irregular practice has, we should hope, been cleared up a little by the debate in Parliament, much obscurity and misunderstanding still persist. It may be well, therefore, to remind our readers of the discussion held on December 9th last by the Marylebone Division of the British Medical Association. The subject was the attitude of the medical profession towards unqualified practice, and Dr. Hawthorne argued most effectively that this must rest upon certain well established principles. The first of these is that the profession cannot allow it to be a safe and wise course for anyone to submit to treatment based upon the diagnosis of a man who has not undergone the discipline of the medical curriculum and passed the professional tests. The second follows from the first: that medical practitioners cannot and will not meet in consultation, for the purpose of diagnosis, any person who has neither the training nor the knowledge to make such consultation useful and fruitful. The third is that the profession refuses to recognize as a philanthropist or benefactor anyone who possesses on his own showing a remedy for disease and yet keeps this secret for his own personal gain. The fourth principle—which we rejoice to find echoed in Mr. Chamberlain's speech—is that no group of unqualified practitioners ought to be allowed to acquire by Government action a status and recognition which would be readily mistaken by the public as a guarantee of efficient training and competence in the diagnosis and treatment of disease. Thus in four negative propositions Dr. Hawthorne defined the attitude of our profession. Meanwhile (he added with wise moderation) medical practitioners, being to some extent interested parties, did not ask for a legal monopoly in the relief of suffering, but would try to keep an open mind towards knowledge, from whatever source it came.

The chairman of the meeting, Lord Dawson, in his summing up, agreed with Dr. Hawthorne that there must be not the smallest concession to unqualified practice on any matter relating to diagnosis; but the question of treatment raised other considerations. With medicine ever widening its bounds it might, Lord Dawson thought, be necessary in some branches to employ technicians, strictly under medical supervision, who were not themselves medical men. The general control of all the means of treatment must

be maintained by an educated and responsible medical profession, though the actual carrying out of certain methods of treatment could perhaps be delegated under proper supervision—as is, in fact, in some directions the present practice. This, however, would not meet the pretensions of osteopaths and their friends, whose demand is for equal status with the registered practitioner. They have had a public rebuff from the Minister of Health; but, unless we are much mistaken, they will try again, and the medical profession must keep on the watch. This watch is necessary, not primarily or mainly in the interests of the profession (for medical history shows that theories and practices based on altogether unscientific foundations have no very long life), but in the interests of the public, who, though it may be at liberty to submit itself to the manifest and prevalent dangers of unqualified practice, should be protected from the danger of doing so unwittingly.

WILLIAM BATESON.

ENGLISH biology has sustained a great loss by the death, on February 8th, of Professor William Bateson, F.R.S., for he was acknowledged to be one of the leaders of scientific thought in this country. Although his most important and striking work was in connexion with heredity and evolution, Bateson's first studies after a brilliant academic career at Cambridge were in the field of embryology, where he came under the influence of Francis Balfour. He worked both at Cambridge and later in America at certain problems in morphology, but the broader questions of evolution attracted him, and he turned his attention to the study of variations. This work often necessitated his travelling wide afield, for he would seek to investigate cases wherever he heard they might be found, and in 1894 his brilliant *Materials for the Study of Variation* gave the first results of his work. The facts he described in this book and the masterly theories he based upon them came as something of a shock to the then prevalent school of thought, for Bateson showed that Nature often proceeds by discontinuous variations, a view which was strikingly confirmed by the discovery of Mendel's famous papers a few years later. Bateson's ideas were so similar to those which Mendel set forth that he was at once convinced of the correctness of "Mendelism," despite the hostility of most professional biologists, and he proceeded by laborious experiment, in his own garden at Grantchester and in the Cambridge Botanical Garden, to obtain material which would extend and confirm Mendel's views. In 1904, at the Cambridge meeting of the British Association, Bateson, as president of the Zoological Section, opened an important discussion on Mendelism, and so striking was the work he described and the facts he brought forward that he completely carried a crowded meeting. He had been appointed professor of biology at Cambridge in 1908, but after only a year of office he resigned in order to become director of the John Innes Horticultural Institute at Merton Park, where he had more ample resources and more scope for his work on variation, which proceeded both in his own hands and in those of his enthusiastic followers. Bateson was the son of the Rev. W. H. Bateson, Master of St. John's College, Cambridge, from 1857 to 1861, and he was educated at Rugby and at his father's college. He obtained a first class in the Natural Sciences Tripos, in company with Dr. J. G. Adami and Dr. Henry Head, and was elected to a fellowship at his college. Many honours came to him in later life, for he was twice a medallist of the Royal Society, the recipient of many honorary degrees, and the honorary member of many learned societies both at home and abroad. He was president of the British Association at Melbourne in 1914, and was to have been president of

the Botanical Section this year at Oxford. Bateson's work in biology has been of supreme importance in elucidating many of the problems of evolution. There still remains for the workers who follow him to apply many of his results, some of which have an important bearing on certain unsettled questions in medicine.

TYPHOID FEVER IN EUROPE.

It has been the practice of the *Journal of the American Medical Association* to give an annual survey of the mortality from typhoid fever in the large cities of the United States, and in the issue of December 12th, 1925, it recorded by way of comparison the condition in this respect of certain large European cities with populations exceeding 100,000. It is gratifying to find it stated of Great Britain that no other country can show so long a list of large cities free from a single typhoid death. No fewer than fifteen of our cities, with a total population of 2,256,700, had a perfectly clear record for 1924. In the list of British cities no municipality had a rate over 5 per 100,000 population in 1924, and all but three had a rate of less than 2. London reported a typhoid rate of only 1.1 for 1924—a record exceeded by seven American cities in the same year. In Germany only two out of thirty-six large cities—Chemnitz and Carlsruhe—reported no typhoid deaths, and more than half the German cities had rates over 2; six had rates over 5. On the whole the rates in German cities were not much lower than those in the large cities in the United States under similar climatic conditions. Typhoid rates in the French cities were somewhat higher on the average than those of Great Britain or Germany. In general the northern French cities had lower rates than those further south, the extremes being represented by Strasbourg (0.6) and Marseilles (31). In the rest of Europe there was a general, though not exact, correspondence between the latitude of the city and the typhoid rate, Southern Europe having a higher average typhoid mortality than the northern part, as is the case in the United States. The Russian and Polish cities, especially Moscow, Ufa, Lwow, and Vilna, appear to suffer more from typhoid than any other European countries in the same latitude. In many parts of Europe the typhoid rate in 1924 was notably higher than in 1923, especially in the Baltic regions.

EVOLUTION OF PREHISTORIC MAN.

THE controversies which surround the various finds bearing upon the antiquity of man were illustrated at a meeting of the Eugenics Education Society on February 12th, when Dr. H. F. Humphreys gave an able address on the evolution of the prehistoric races. His chairman, Professor E. W. MacBride, F.R.S., however, thought that Dr. Humphreys took too optimistic a view with regard to the well known specimens of supposedly extinct species of the human family. Professor MacBride believed the lower jaw of the Piltdown fragments to be almost certainly that of a chimpanzee which, being in the vicinity, had been supposed to belong to the otherwise human skull; the Pithecanthropus of Java was extremely unlikely to have been a man at all, but only a gigantic species of gibbon; and as to the Rhodesian skull, he believed it to be the remains of a comparatively modern type of savage. Dr. Humphreys, in the course of his address, said that all undoubted traces of the human family fell in the Pleistocene period of the geologists, which preceded the Holocene or recent period. The Pleistocene period consisted of violent oscillations of climate, with two ice ages, and a genial age between them. The earliest known traces of *Homo sapiens* dated from the later part of this period. This prehistoric man had skill in fashioning flint instruments, an understanding and control of fire, a measure of

artistic skill, and the habit of burying his dead, which argued imagination and some belief in a future life. In physical development he was not inferior to the civilized man of to-day, and his cranial capacity even exceeded the modern average. He represented, not a human archetype, but merely one of the varieties into which the human species had already diverged. Since his time the human race had progressed mainly by the addition of one invention to another—in other words, modern man, compared with these ancestors, was not biologically a superman, but simply the heir of the ages. In the second ice age of the Pleistocene period *Homo sapiens* was not traced, and Europe was apparently then peopled by the Neanderthal man, another species of the same genus. The Neanderthal man walked with a less erect posture and a shuffling gait, his eyebrows had protruding ridges, and the frontal area of his brain was small. In the genial age between the first and second ice ages the evidence of human existence consisted only of flint instruments and a few fossils. The Piltdown and Heidelberg skulls were generally regarded as belonging to this period. The Piltdown man had a characteristically human cranium, though of small size, but the lower jaw was characteristic of the chimpanzee. The Heidelberg skull was at least as old as the Piltdown, and showed characteristics intermediate between the ape and man; the teeth, however, were entirely human. The Rhodesian skull was discovered under conditions which made it impossible to assign the place of the skull in geological time, and although it was a lower type than Neanderthal man it might have been more recent. In the case of the Pithecanthropus of Java, while the cranial capacity was halfway between the averages of apes and man, the remains were too fragmentary to determine the relation of this creature to man, whose direct ancestor it was unlikely to have been. The Pliocene period, preceding the Pleistocene, was a blank in the history of man, and it seemed likely that the genus *homo*, like many other living genera, was a creation of Pleistocene time. From the Miocene period, preceding the Pliocene, dated the earliest remains yet discovered of the large anthropoid apes, and there was good reason to suppose that some species of ape of the Miocene period became the progenitors of the human family. These creatures seemed to have been less brutal in their character than the later apes, they had not such excessive length of arm or canine tusks, and probably their foreheads were less receding. In the relatively refined characteristics of the young chimpanzee, repeating the history of the race, there existed a truer picture of the ancestor than in the brutal adult form. From this origin, in Miocene times, the family would branch into different genera, of which several, perhaps all, would acquire the habit of walking erect and the rudiments of speech. Of these genera to-day *Homo sapiens* was the sole survivor, and of his actual ancestors no remains had been discovered, for all the skulls mentioned were those of collaterals. In tracing the evolution from the ape to man, Dr. Humphreys said that regard must be paid to the beginnings of the primates or monkey family, which, with the insectivora, was the oldest existing order of mammals, and was represented even at the beginning of the Eocene period by some primitive lemurs. The ancestors of the primates lived in trees, where their impressions would no longer be dominated, as in the case of other mammals, by the sense of smell, and there would be a development of the centres of sight and, in a less degree, of hearing, also of the portion of the brain concerned with the co-ordination of complicated muscular movements. At some time, possibly in the Miocene period, the ape-like ancestors of the human family, perhaps on account of climatic change, forsook their forest home and their vegetarian habits, and took to hunting wild game in more open country. The erect posture would help them to run faster, and would set free

the hand as an auxiliary hunting or sexual weapon, thereby superseding the canine tusks. Single-handed the ape could not run down game, and the combination of the animals into a pack, which greatly enhanced the chances of success, would involve subordination to a strong and cunning leader, a primitive discipline and strategy, and a system of signalling and calling. The primitive ape had also to make some provision for females and young who could not hunt, and this might lead to some moral development. But Dr. Humphreys had to admit that all this did not account for the high powers of imagination and abstract thinking of which man was the sole possessor.

INTERNATIONAL SOCIETY OF SURGERY.

The seventh Congress of the International Society of Surgery (as announced in our issue of January 23rd) will be held in Rome from April 7th to 10th of this year. Professor Giordano, the well known surgeon of Venice, is the president. The subjects for discussion and the speakers are as follows:—(1) Radium treatment of uterine cancer: Drs. Beuttner (Geneva), Donaldson and Forsdike (London), Pestolozza (Rome), Recasens (Madrid), and Regaud (Paris). (2) Abscess of the liver: Drs. Dominici (Rome) and Petridis (Alexandria). (3) Treatment of cerebral tumours: Drs. Adson (Mayo Clinic), Bastianelli (Rome), do Martel (Paris), Percy Sargent (London), Brun (Lucerne), and Lozano (Saragossa). (4) Surgery of the spleen: Drs. Cortes-Illado (Seville), Henschen (St. Gall), Leotta (Bari), Papayannou (Ghezireh), and Patel (Lyons). (5) Late results of Jacksonian epilepsy: Dr. Leriche (Strasbourg). Operations will be performed in the hospitals on two mornings. The social side of the Congress comprises receptions by the Governor of Rome and the President of the Congress, a banquet given by the Italian members, and an excursion to Tivoli. Two tours in connexion with the Congress have been arranged: (1) A tour to Milan, Venice, Padua, Bologna, and Florence, starting from London on March 29th and arriving in Rome for the commencement of the Congress. (2) A tour to Naples, Pompeii, Vesuvius, and the Isle of Capri, from April 13th to 16th. Messrs. Thomas Cook and Son, Ltd., have been appointed official agents, and will quote inclusive fares based on reductions granted by the Italian State Railways to members of the Congress. Members may be accompanied by their wives and families. Further particulars may be obtained from Mr. J. E. H. Roberts, 26, Harley Street, W.1, the British delegate.

A SIGHT-TESTING OPTICIANS' BILL.

SIGHT-TESTING opticians just now are very busy preparing draft bills for Parliament. There are several organizations of opticians, and these seem to vie with each other in putting together and issuing these "bills" which are to be laid before the Legislature. The latest of them is issued by the "Joint Council of Qualified Opticians." It is marked in heavy black type on the front page "Draft No. 11," so it would appear that the officers of this joint council must have had some practice in drafting bills. The present draft is a massive document of twenty pages containing twenty clauses and three schedules. Its title indicates its purpose: "To secure the registration of optical practitioners and to regulate the practice of sight-testing and optical dispensing, and for the purposes incidental thereto." Plainly put, the desire of the sight-testing opticians is to secure control of the practice of what they describe as optometry, and to prohibit anyone else doing this work. Optometry includes "the giving of any treatment, advice, or attendance on or to any person as preparatory to or for the purpose of or in connexion with any of the processes aforesaid, and any treatment, advice, or attendance usually given by optometrists or refractionists." Such a definition would cover the administration of drugs

by persons ignorant of their therapeutic power or of how to check their effect in untoward cases. Besides this the draft bill seeks to prohibit any person selling spectacles (other than goggles!) unless he is registered on a supplementary register for dispensing opticians. The optometrists may, of course, sell their own spectacles to the persons for whom they prescribe them. The draft bill prescribes heavy penalties for breach of the regulations. Apparently registered medical practitioners would also be involved in these penalties, for they are not exempt from its provisions. It is true that Clause 1, Section (4) provides that "Nothing in the Act shall operate to prevent the practice of optometry by a registered medical ophthalmic specialist." But there is nothing to show what is meant by a registered medical ophthalmic specialist, and we fail to recognize this term as one current in medical circles or known to the General Medical Council. But the sight-testing opticians are not content with all that, with an exclusive register and heavy penalties against offenders; they desire more effective powers. A Central Optical Board is to be constituted to guard the register. The first board is to consist of twenty-five persons. Two members are to be appointed by the General Medical Council (and this is the only mention of the medical control of the affairs embraced in the draft bill); five appointed by certain universities; fifteen elected by the optometrists on the temporary register; and three appointed by the Minister of Health, all of whom must be opticians, sight-testers or otherwise. A truly liberal constitution for a proposed national service! But Draft No. 11 may be followed by further drafts. The general subject of irregular practice is discussed in a leading article at page 337. In regard to this particular branch of unqualified practice, we hold that the aims set out are not conducive to the public good. It is against the interest of the public that an inferior order of quasi-medical practitioners should be recognized by law for the treatment of conditions of disease or abnormality. Sight, the chief sense organ of man, is far too precious to be left to the ministrations of persons untrained in the knowledge of the human body as a whole. To do this is to incur a risk that we know to be unjustifiable. For the State to set up a register and establish a close corporation of untrained, or at best half-trained, persons would be to assure its citizens, on the authority of Parliament, that there is no such risk. The position of the medical profession in this matter is summed up in the decision of the Representative Body of the British Medical Association in 1923: "That any State recognition of sight-testing by persons not possessed of a medical qualification would not be in the interests of the community, and ought to be opposed in the strongest possible manner."

ROBERT BURNS: DIATHESIS OR DRINK?

THE 25th of January sees year by year the foaming spate of Burns oratory go thundering to the sea of oblivion, and—*Dieu soit loué!*—in spite of it all the serene light of the man's genius shines without a flicker. Books are written telling the "truth" about him, "messages" are extracted by perfervid gentlemen in white ties (especially those of the type Mark Twain called "the pisonest kind"), who, to their own satisfaction at least, prove him to have been a Socialist, a Unitarian, or whatever their taste and fancy direct. But hardly a speech or a book appears without some fellow sinner indulging in an apologia for the alleged dissolute habits of the poet. Had he dissolute habits? This is the question that Sir James Crichton-Browne sets himself to answer in a little book lately published,¹ and he traces the origin of the accusation to the poet's first biographer, Dr. Currie. After the lapse of years it seems fitting that the venom introduced by one medical man

should receive its antidote from another. Currie, we gather, was a well-meaning man with a strong hereditary strain in him of the "unco-guid," aggravated by an inability to see more than one side of a question. Like some other fierce teetotalers, he seemed to smell drink in almost everything and everybody. To him, then, our author attributes the original tainting of the stream of biography, as so many of the later biographers drew without question on the authority of Currie. The thesis Sir James Crichton-Browne sets out to prove is that (while acknowledging occasional lapses on the part of Burns in the way of over-indulgence in liquor at a time when such lapses were held to be more venial than now) the poet can by no means be classed as an habitual drunkard; and that this is confirmed by the life of toil he led, first as an agriculturist and later as an exciseman, when his work in that capacity was approved by his superiors and at no time called for disciplinary interference. Wilson has said that "not a man could be found in Dumfries who had ever seen Burns intoxicated." Further, much of the ill health from which he suffered, and his subsequent death, were due not, as has hitherto been generally supposed, to alcoholic excess, but to some form of rheumatism, which had been slowly but surely undermining his constitution for twenty years. In support of this belief Sir James Crichton-Browne gives chapter and verse throughout his book, and criticizes the treatment given to the patient by his last medical attendant, Dr. Maxwell, who sent a sufferer from valvular disease of the heart to the Brown-Well Spa, where, "lodged in a thatched cottage with only a but and a ben and partaking of nothing but porridge and milk," the unfortunate patient was further recommended to indulge in sea bathing and horse exercise. Naturally "he got steadily worse while he was there, had a sharp feverish attack before he left it, and returned home from it" to die three days later. One other medical point made by the author is that Burns, when he refers (as he frequently does in his letters) to his "hypochondriasis," was not using the word "in the medical sense of the term, that is to say morbid apprehensions and delusions about his bodily health," but to signify that he suffered "from an inherited predisposition to nervous depression, aggravated by the pressure of incessant and wearing toil, with inferior and perhaps scanty nutriment in his boyhood and youth. Thus came his stooping shoulders." Hence also came "the self-accusations which are so profusely scattered through the letters and poems, many of which were groundless or grotesque amplifications of venial offences or mere anguished exclamations." A good book—appearing at an appropriate season—and a charitable one. Every Scot will wish to have it on his shelf among his Burns literature.

FIRST AID FOR BORROWERS.

THAT moneylending is a profitable business is shown by the statistical report of new companies registered in England during the year 1925, published by Jordan and Sons, Ltd., company registration agents, Chancery Lane. From this report it appears that thirty-seven new money-lending concerns were registered, with a total capital of £150,000. The subject may interest medical men since Mr. H. H. Kelsey, in his pamphlet *3,000%, or the Borrower's Book on Money-Lending*,¹ places doctors third on the list of favourite victims of the moneylender. They give precedence only to expectant heirs and clergymen. We confess that this surprises us; but if, as Mr. Kelsey says, the existence of 30,000 moneylenders involves a borrowing population of at least 3,000,000, there may well be many doctors among the gullible. The moneylender, it appears, builds his trade on the seemingly contradictory

¹ *Burns from a New Point of View*. By Sir James Crichton-Browne. London: Hodder and Stoughton, Ltd. 1925. (Cr. 8vo, pp. 92. 3s. 6d. net.)

¹ *3,000%, or the Borrower's Book on Money-Lending*, 1926. By H. H. Kelsey. London: Anti-Moneylending Association, Ltd. 1926. (Demy 8vo, pp. 40. 2s. net.)

supports of privacy and publicity. He snares the victim's confidence by the "strict privacy" of his methods, and bludgeons him into exorbitant repayment by blackmailing threats of publicity. Thus the village doctor may receive a telegram demanding money or threatening proceedings. Mr. Kelsey affirms that moneylenders do not lend without security; their security in most cases is the powerful weapon of blackmail. So that the first advice given in this book is not to be afraid of publicity. Threaten to deal with such action as if it were blackmail, and the moneylender will show little fight. In fact, the keynote of Mr. Kelsey's advice to the borrower is to get his blow in first. If the borrower expects to be sued, let him (if he can) tender the money borrowed and a fair rate of interest. If the tender is made the moneylender rarely sues: he will have to pay the borrower's costs in the event of not recovering more than the amount tendered. If the moneylender holds a bill of sale, and is threatening to seize the furniture, let the borrower issue a writ claiming relief under the Moneylenders Act and an injunction against the seizure: the moneylender will promptly come round to negotiate a settlement. It is suggested by Mr. Kelsey that the law is still too much in favour of the moneylender. Thus, under the Moneylenders Act of 1900, even if the moneylender's interest is held to be harsh, unconscionable, and excessive, and is cut down by the court, the borrower has to pay the costs of the action unless before the action he has tendered or paid into court the sum borrowed and a reasonable amount for interest; and these costs frequently amount to more than the relief that has been granted to the borrower by the court. As the moneylender's solicitor is said not to be paid by the moneylender, but to trust to getting his costs out of the borrower, the door is open to all sorts of shady practices. Thus subpoenas are served upon people whom the borrower would least like to be made aware of his troubles. There is no real intention of calling these people as witnesses; it is hoped that the fear of the borrower may compel him to pay up rather than expose his father or employer to the trouble of attending the court. Frequently the moneylender will try to induce the borrower to sign a statutory declaration, in the hope that he will make an inaccurate declaration, and thus furnish the moneylender with the further weapon of a threat of criminal prosecution. Mr. Kelsey would remedy these injustices by restricting the present powers of a moneylender under a bill of sale, by making the moneylender pay all costs if his interest is cut down by the court, by restricting the issue of subpoenas to material witnesses only, and by making statutory declarations in moneylending transactions illegal. At the same time, Mr. Kelsey admits that in remedying the injustices to borrowers the moneylending business would probably be extinguished. He says that under his proposed amendment of the Moneylenders Act no moneylender would ever sue unless he knew his interest was sufficiently reasonable for no judge to interfere with it. But if he cannot sue no moneylender will lend; and as, under Mr. Kelsey's amendment, if the interest is cut down the moneylender will be out of pocket through having to pay the borrower's costs, the moneylender will be put out of business. Whether this is desirable or not we are not prepared, upon present evidence, to say. Anyhow, the moneylender continues to flourish, notwithstanding the weighty words of Mr. Justice Mathew in the report of the Moneylending Commission of 1898. In certain cases, Mr. Justice Mathew said, the borrower is placed in a position where it is a question of "his money or his life." "The moneylender may do with him as he pleases. That is not a position in which one man ought to be placed by the law with reference to another; he ought not to have that power of coercion; he ought not to have his fellow creature in that state of subjection." However wise the advice, "Neither a borrower nor a lender be," we are afraid that there will

always be some men so hard pressed as not to know where to turn for help. Mr. Kelsey suggests the experiment of founding a philanthropic institution for lending money at a fixed rate of 10 per cent. per annum; but he sorrowfully admits that the bad debts would probably be considerable.

A NEW HEART JOURNAL.

THERE have recently come to hand the first two numbers of the *American Heart Journal*, a new periodical issued under the editorial direction of the American Heart Association. It has been established in response to a demand by physicians in the United States for a journal covering this field of medicine, and in the confident expectation that it might be of much assistance in furthering the objects of the association. While primarily clinical in character, the *American Heart Journal* aims at embracing all phases of the subject, and will embody the results of recent researches, as well as dealing with the preventive aspects. It should attract, not only the cardiologist specialist, but also the general physician. The numbers before us contain, among others, articles on such diverse subjects as prognosis in subacute bacterial endocarditis; the selection of patients with angina pectoris for sympathectomy; the heart in myxoedema; the circulation of the heart valves; vaso-dilatation following sympathetic neurectomy; the independence of electrical and mechanical reactions in the mammalian heart; basal metabolism in organic heart disease. Small sections are devoted to society transactions and reviews and abstracts of current literature. The journal will appear every second month, though later it is proposed to make it a monthly periodical. It is published by the C. V. Mosby Company, St. Louis (H. Kimpton, London), and the price is \$1.25.

THE spring lectures at the Royal College of Physicians of London will commence on March 2nd, when Professor W. W. C. Topley will deliver the first of his three Milroy Lectures on experimental epidemiology; the dates of the second and third are March 4th and 9th. The Goulstonian Lectures will be delivered by Dr. Bernard Hart on March 11th, 16th, and 18th; his subject is the development of psycho-pathology and its place in medicine. Sir Thomas Horder, Bt., will give the Lumleian Lectures, on endocarditis, on March 23rd, 25th, and 30th. The Oliver-Sharpey Lectures, on carbohydrate metabolism in health and disease, will be given on May 4th and 6th by Professor Hugh Maclean. Sir Thomas Lewis's Croonian Lectures, entitled "Observations upon blood vessels of the human skin," will be given on June 8th, 10th, 15th, and 17th. All lectures will be delivered at 5 p.m. at the College, Pall Mall East. Members of the medical profession will be admitted to them on presentation of card.

THE series of Hunterian Lectures on the fossil remains of ape and man and their bearing on man's evolution, by Sir Arthur Keith, which had to be interrupted owing to the lecturer's illness, will be delivered in the theatre of the Royal College of Surgeons of England, Lincoln's Inn Fields, W.C., on February 22nd, 24th, and 26th, at 5 p.m. The first lecture will deal with the Taungs anthropoid and its zoological and geological position; the second with the fossil anthropoids of Europe and of Asia; and the last with the Kiru gorilla and its bearings on the problems of human evolution. The lectures will be illustrated by casts and preparations from the museum and by lantern slides. The spring course of museum demonstrations at the College will commence on March 12th at 5 p.m., when Sir Arthur Keith will demonstrate parts concerned in the secretion and absorption of cerebro-spinal fluid. The demonstrations will be continued on succeeding Mondays and Fridays, at 5 p.m., until Monday, March 29th, when Mr. Shattock will demonstrate pathological conditions of the breast.

Scotland.

THE MORISON LECTURES.

THE Morison Lectures on mental deficiency before the Royal College of Physicians of Edinburgh will be delivered in the Hall of the College, 9, Queen Street, Edinburgh, by Dr. R. D. Clarkson, on March 1st, 3rd, and 5th, at 5 p.m. The first lecture will deal with the definition of mental deficiency and the classification of mental defectives, the second with the cause of mental deficiency, and the last with the treatment of mental defectives.

MEMORIAL TO SIR WILLIAM MACEWEN.

At a meeting of Glasgow University Court, held on February 11th, a letter was read from Mr. Archibald Young, honorary secretary to the Sir William Macewen Memorial Fund. The letter stated that it was intended to procure a bust by a sculptor of the first rank for presentation to the university and a replica to be presented to Lady Macewen. It was also intended to establish a Macewen memorial lecture and, if sufficient funds were obtained, to found a Macewen medal or prize in the class of surgery. The letter added that the bust and replica were now completed, and that the committee had in hand a balance of £1,400, of which probably £1,200 would be assigned for the establishment and endowment of the Macewen memorial lecture and the remainder for the establishment of a memorial medal. It was agreed that the bust and replica should be presented on Commemoration day, June 23rd, and that the first memorial lecture would be given at the same time, and thereafter biannually.

MATERNAL MORTALITY.

A lecture entitled "The problem of our high maternal and infantile mortality and morbidity" was delivered on February 11th by Professor B. P. Watson, in the Gartshore Hall, Edinburgh, under the auspices of the Edinburgh Women Citizens' Association. Lady Findlay, who presided, said that she hoped public opinion might be stimulated to try to remove some of the causes of the high mortality. Children had wonderful vitality, and given a normal, healthy environment would thrive without much care or attention. Unfortunately, however, the conditions under which children lived to-day were far from being normal, as they were deprived of light and air under the miserable housing conditions of our cities. In her opinion most of our social evils came from the housing conditions in overcrowded cities. Professor Watson pointed out that the maternal death rate in Scotland was 6.2 per 1,000. Scotland was in the unenviable position of having one of the highest maternal death rates, the lowest death rate being in the Netherlands and the highest in Spain. Under present economic conditions it was not possible that every child should be born in a properly equipped institution, but he hoped the day would come when that would be the case. Preventive medicine as applied to midwifery consisted of proper ante-natal care. Clinics should be established in every large centre of population. Ante-natal care had really begun in Edinburgh under the late Dr. J. W. Ballantyne, who was the first to see the tremendous importance of this aspect of preventive medicine. The first ante-natal bed to be endowed had been in the Royal Maternity Hospital at Edinburgh, but more hospital accommodation was needed for maternity work. Large sums of money had been given to general hospitals and infirmaries, but the maternity hospitals had been left out for the most part. In his opinion, the modern tendency to link up the maternity hospital with the general hospital was to the good. In Edinburgh an affiliation between the new maternity hospital and the Royal Infirmary would be welcomed, and he thought this would bring about a diminution in cost and an increase in efficiency.

CARNEGIE TRUST ANNUAL REPORT.

The annual meeting of the Carnegie Trust for the Scottish Universities was held on February 10th at the

Universities' Bureau, Russell Square, London; Lord Sands presided. The executive committee to the trustees, in presenting the twenty-fourth annual report, indicated that during the past five years private benefactions to the four Scottish Universities had exceeded £800,000, but that there were few sections of their activities which had not called for some further advances. A committee of visitation had been appointed to consider and report upon the various claims of the universities, and a considerable amount of assistance had been given to university hostels. A sum of £20,000 had been allocated to St. Andrews University towards the provision of a residence for male students at St. Andrews, £10,000 to Edinburgh University for hostels for men and women, and £20,000 to Aberdeen University towards a new students' union. Several institutions which had not previously benefited had been assisted, such as the Glasgow and West of Scotland Commercial College, the Scottish Marine Biological Station at Millport, the Rowett Institution at Aberdeen, and the Animal Breeding Research Department at Edinburgh. The various distributions by the Trust arranged to cover the period from October, 1902, to September, 1930; included grants amounting to £1,394,029, which included grants for libraries, £127,925; for buildings and permanent equipment, £817,267; and for endowment of chairs and lectureships and similar general purposes, £448,837. By the end of 1930 fourteen chairs and thirty-one lectureships would have been endowed largely by the help of grants from the Trust. The sums granted by the Trust for endowment of research during 1924-25 amounted to £18,267. At Edinburgh University it had been proposed that the whole of the grant for five years, other than the library grant, should be devoted to payment of the cost of erection of the new chemical buildings, towards which the Trust had already contributed £75,000, and upon full consideration the committee recommended the executive to meet, as far as possible, the views of the university in this matter. A grant of £18,000 was recommended for the provision of new buildings for the natural history department. The committee recommended that £10,000 should be granted towards the cost of a hostel for male students in George Square and towards the completion of the block of hostels for women. The committee also recommended a supplementary grant of £25,000 towards the cost of erection of the chemical laboratories, which brought up the total contribution of the Trust to this department to the sum of £100,000.

Lord Sands, in moving the adoption of the annual report, emphasized the principle that the Carnegie Trust's grants must be regarded as capital grants and not as annual payments. A grant was given to encourage some new activity, and under their system was payable in five yearly instalments. There had been an erroneous tendency to look upon payments coming in this way as annual subventions which might be expected to be renewed for the next five years. The executive committee, however, was of opinion that this misconception must be corrected, and that the general principle that he had mentioned must be adhered to, whether in the case of small or large grants, or as concerning extra-mural institutions and universities. An annual sum of approximately £18,000 was devoted to grants in aid of research, in payment of part-time researchers who were part-time university lecturers, and in subsidies to graduates who for a year or two devoted themselves exclusively to training in research. Such grants had been rewarded by the immediate valuable results of work carried on with their assistance, and also by the undoubted subsequent success of many of their students in different spheres of research. Discussing the payment of class fees, Lord Sands stated that the number of applicants was so great that the contribution had had to be reduced in amount and the executive had been obliged to tighten up the test of family necessity. It might be necessary more fully to reconsider this matter, for so far the result had been disappointing. At present the most which the Trust was able to contribute was less than half of the total fees in the case of each student. During the past academic year the number of Carnegie students was 4,543, of whom 2,714 were men and 1,829 women, this number being over 70 per cent. of the whole of the Scottish students who

were educationally eligible for assistance. Students were assisted in virtue of a declaration by a parent or guardian that his circumstances were such that, without the assistance of the Trust, he would be unable to provide university education for his child or ward. It was startling that to the extent of 70 per cent. of Scottish students the parents were in a position of being able to furnish seven-eighths, but quite unable to provide the last eighth, which half of the fees might be taken to represent. These figures created an uneasy impression that there must be a very considerable number of cases where the declaration was signed without a due sense of responsibility by persons who in other relations would not seek to obtain assistance from public funds by untrue declaration. In conclusion, the chairman mentioned that during the past year £1,416 had been repaid by thirty-one former beneficiaries, which was the second highest amount received in any one year. The repayments came from all parts of the world, and the number coming from remote places seemed to suggest that sojourn far away might have a quickening effect on the conscience.

Lord Haldane expressed the opinion that it was essential that a trust of this kind should exist, not so much for the purpose of keeping up students or chairs, but for stimulating the growth of learning, which could best be done by bringing new people and new institutions into existence on the footing that as they gained vitality they would maintain themselves from other sources than the Trust. He was in favour of this Trust assisting research largely, but he believed that many people were apt to be misled as to their capacity to undertake research. He believed that research, like poetry, required an inherent imagination, and was in many ways a gift of Nature. Principal Sir James Irvine thought he could almost put a quantitative figure on Lord Haldane's statement. Out of 100 graduates with first-class honours, only some 20 were suitable for trial in research work; of these 20 in turn, after two years' experience, about 5 were worthy of encouragement. He thought that this was demonstrable from the figures of their own Trust and from those of the Council of Scientific and Industrial Research.

Principal Sir Donald MacAlister hoped the valuable work that had been done in improving the students' unions and in building hostels would receive due credit from the Scottish public. He referred to the falling off in the numbers of medical students, and especially those of women medical students. He pointed out that immediately after the war, when the men of the medical profession had been called to serve under the State and the demand for women to take their place was very great, a suggestion went abroad that now was the time for women to go into the medical profession, and they proceeded in a somewhat precipitate manner to flock into medical schools, rather to the embarrassment of the teachers. Some of them had foreseen the inevitable result, and warned the women again and again, but they would not listen. As soon as the doctors came back from the war it was obvious that they would fall into their places, and the women who had graduated were displaced. These facts had verified the prophecies that were made, and demonstrated that there were not such a number of sheltered places in the medical profession as the women thought.

NEW CHAIR OF BACTERIOLOGY AT ABERDEEN.

At a meeting of Aberdeen University Court, held on February 9th, Dr. John Cruickshank, reader in bacteriology in Aberdeen University, was appointed to the new chair of bacteriology at Aberdeen as from October 1st, 1926. Dr. Cruickshank is a native of Glasgow, and was educated at Alan Glen's School, Glasgow, and at the University of Glasgow, where he graduated with honours in 1908, gaining at the same time the Brunton Memorial Prize for the most distinguished graduate of the year. After graduation he became assistant to Professor Robert Muir in the department of pathology at Glasgow University, and acted in this capacity for three years. He was awarded the John Reid Memorial Prize for research work, and in 1912 was appointed bacteriologist to the Crichton Royal Institution, Dumfries. During his tenure of this post he was awarded the Foulis Memorial Prize for

research work into the causation of mental disease. In 1913 he took the M.D. degree with honours, gaining the Bellahouston Gold Medal for his thesis. During the war Dr. Cruickshank was for a time in charge of a mobile bacteriological laboratory in France, and acted also as assistant adviser in pathology to the Third Army. He has published the results of numerous researches especially connected with the subject of immunity.

England and Wales.

BRITISH INDUSTRIES FAIR.

THE British Industries Fair, which opened in London and Birmingham on February 15th, affords a comprehensive display of British industrial products. The London section, which is housed at the White City, includes fifteen separate departments, each devoted to a special line of production; the number of exhibitors is over 750, and a stand space of over 150,000 sq. ft. has been allotted. One of the most important groups is that devoted to chemicals and drugs, to which some sixty manufacturing concerns contribute. It is stated that now over one thousand fine chemicals, which were not made in Great Britain previous to the war, are being produced. The chemicals shown include, not only the highly specialized drugs familiar to medicine, but chemicals used in general scientific research, in photography, and for various industrial purposes such as dyeing. The Association of Chemical Manufacturers shows raw materials and intermediate products used in the manufacture of dyestuffs, as well as a specialized range of dyestuffs of great interest. The exhibits of crystals of alum, bichromates, and cyanides call attention to the fact that this country is still pre-eminent in the manufacture of these products. The section of scientific and optical instruments is less complete than that of chemicals and drugs, but it illustrates the remarkable development whereby this country has erected a large and independent optical glass industry of recent years, and there is also an interesting collection of various measuring instruments, such as thermometers, as well as instruments of special use for the airman. Other sections of the Fair deal with food products (and here one notes that the methods of packing become more ingenious and pleasing), leather goods, cutlery, furniture, and clothing, and an inevitable innovation is a special section for wireless. The Fair, admission to which on previous occasions has been granted only to those on business, is now open to the public in the evenings, and a visit can be recommended as a corrective to pessimism about the national future in industry.

THE POPULATION QUESTION.

At a meeting of the Nottingham Medico-Chirurgical Society on February 3rd, with the President, Mr. H. Bell Tawse, in the chair, Sir James Barr (Liverpool) delivered an address on the question of population, with special reference to heredity and birth control. He contended that despite the more or less continuous outcry in the daily press about the falling birth rate, what the country really needed was quality, not quantity. The lecturer regarded all deaths under 15 years as a dead loss to the State, and from those under 20 years there was no profit, as up to that age each individual cost on an average £500 to £400 in food, clothing, education, and sickness. He quoted, from the 1923 Report of the Principal Medical Officer to the Board of Education that 48 per cent. of elementary school children were suffering from physical defects of varying degree, and about 2 per cent. from malnutrition, heart disease, anaemia, or deformities. As a whole this accounted for 100,000 victims. He agreed that the welfare centres did excellent work; but the period of a child's life from 2 to 5 years—aptly described as No Man's Land—was entirely devoid of supervision, and until this was rectified little or no diminution in the number of defects in the elementary school children need be expected. He disagreed with the statement that all these children were born healthy, and held that the majority were by heredity weak, and that the poor vitality was intensified by

unhealthy environment. Feeble-mindedness was a Mendelian recessive which bred true, but many apparently normal individuals had latent taints which cropped up in future generations. After remarking that there were 2,000 more cases of tuberculosis in 1924 than in 1923, he referred to the statement made by the late Dr. D. W. Hunter—that until we had a selective birth rate he would look upon abolition of the tubercle bacillus as a national calamity.

Sir James Barr then passed to the subject of Mendelism, and remarked that he preferred to improve the breed both of plants and of animals rather than deal with their degenerate mutations arising from plasma weakness. He insisted that an "A1 nation," morally, intellectually, and physically, could only be raised by selective breeding. When a nation became overstocked beyond the means of subsistence the unfit got wiped out by war, famine, disease, and pestilence. The least desirable nations of the earth were the most prolific, and most of the world's unrest was due to the fecundity of the women of Russia, India, and Egypt. The Japanese, a very prolific race, were now practising birth control, as there was no outlet for their surplus population. The only hope for the peace of Europe was that the people of Germany might practise birth control and thus keep their population within the means of subsistence. Although it was difficult to know what characters led to the elevation of the race, one could make a start by eliminating those that were not wanted—for example, idiots, imbeciles, feeble-minded, useless wastrels, habitual criminals, etc. Birth control he considered essential for the masses if the poor were not always to be kept in poverty, in order to provide cheap labour. There was plenty of virility in the working class—as much as in any other grade of society—and if they were not kept in gross ignorance of sexual matters and economic laws they would raise themselves and their families in the social scale by putting no limit on output, except the human output. The lecturer concluded with a tribute to New Zealand, where, although birth control was practised, the birth rate was 21.6 per 1,000 of population, as against 18.8 in England. The address was discussed by the President (Mr. Bell Tawse), Drs. Watson, Newth, Hamilton, Flint, Robinson, and Miss Sarah Gray.

THE ROYAL ALBERT INSTITUTION, LANCASTER.

The Royal Albert Institution was established by voluntary effort in 1864 for the care, education, and training of the improvable feeble-minded of all classes belonging to the seven northern counties—Lancashire, Yorkshire, Cheshire, Westmorland, Cumberland, Durham, and Northumberland. Three classes are admitted: private patients at rates from 80 to 250 guineas per annum; patients belonging to one of the seven counties at rates from 40 to 80 guineas; patients elected by subscribers whose friends are unable to meet the lowest payment. Since the opening of the institution 4,286 patients have been admitted, some 10 per cent. of whom have become practically self-supporting under friendly supervision. The institution is subject to inspection by the Commissioners of the Board of Control, and by deputations from boards of guardians and local authorities under the Mental Deficiency Act. The medical superintendent's report shows an increase in the average number of patients from 801 to 806 on March 31st, 1925. The number of deaths recorded was 27. An explanation of the legal procedure necessary for admission to the institution is incorporated in this report.

CARTER HOSPITAL, MIDDLESBROUGH.

The Carter Bequest Hospital, which has recently been opened at Middlesbrough, is essentially a general practitioners' hospital. There is no appointed staff, but the practitioner sends his patients and provides the necessary attendance himself, summoning any specialist he may select. The professional fee is a matter between patient and doctor, and is no concern of the hospital management. In addition to four wards, each with ten beds, single private rooms are available at a charge of three guineas weekly. The administrative block, uniting the two ward blocks, contains reception rooms, accommodation for the

matron and nurses, a dispensary, and a pathological laboratory. The operating block, reached by a connecting corridor, is placed behind the ward blocks, and includes operating, anaesthetic, x-ray, and surgeon's rooms. Each ten-bed ward is fitted with a verandah on to which the patient's bed can be wheeled. Although this hospital was originally planned towards the end of the last century, its erection has been delayed by the need for obtaining a larger sum than that primarily available. The actual building was begun in March, 1924, and the hospital was completed in October, 1925.

LONDON COUNTY COUNCIL.

The Mental Hospitals Committee of the London County Council has not felt justified in assenting to a request voiced in the council that butter be generally substituted for margarine for the table use of mental hospital patients. It has, however, instructed medical superintendents that when there is any shortage of the uncooked vegetables, salads, and fresh fruit usually available as part of the ordinary dietary, and there is any fear that in consequence patients may be adversely affected in health, the vitamin A content of the dietary may be supplemented by substituting butter for margarine. The view of the committee is that the dietary at present in force, which was considerably improved two years ago, having regard to the provision it makes for the issue of fat meat and green vegetables, cannot be said to be inadequate in the provision of vitamin A generally. The London County Council, in furtherance of a scheme for additional accommodation for epileptic children, has arranged with the managers of the Lingfield epileptic colony (Surrey) for the enlargement of that institution so that eighty new vacancies may be available for London children—forty-eight for boys and thirty-two for girls.

Correspondence.

UNQUALIFIED MEDICAL PRACTICE.

SIR,—Under the heading "Medical Notes in Parliament" in your issue of February 13th (p. 306) this statement occurs: "In putting down his motion on unqualified practice Dr. Graham Little did not act for, or in consultation with, the Medical Committee of the House of Commons." I was unable to consult my medical colleagues in the House, because I had only two hours—between 8 and 10 p.m.—in which to choose the subject of my motion. My choice was made because I had read and written much on the position of unqualified medical practice, with special reference to osteopaths.

This subject had, within the last few months, been very freely discussed in medical circles in London—for example, at the Medical Society, the Harveian Society, and others. I considered that it would be useful to "feel the pulse" of the House of Commons regarding the admission to practice of osteopaths; to be forewarned as to the strength of one's opponents is to be forearmed. A private member's motion (such as mine was) seldom goes to a division, and is usually regarded as a means of taking the opinion of the House without action following upon it, so that no serious results were to be feared. My position as an Independent member, returned by a university with a very large and important medical electorate, whom I represent upon the Senate as well as in Parliament, made it more easy for me to take a step which a strict party man might have found it desirable to avoid; and I may say that my postbag since Tuesday has brought me many assurances that my constituents have approved my action. I would quote a typical congratulatory statement from one of these letters, written by one of the most distinguished medical graduates in the University:

"It is generally known and felt that you took an opportunity to put up a motion with which all reasonable people agree; made your opponents expose their very bad hand, and drew a most important statement of policy from the Minister of Health."

The motion was talked out by one of our medical members in agreement with the front Government bench, after the very clear and important statement of the Minister of Health, whose contemptuous rejection of the claim for the registration of osteopaths upon American certificates more than met our chief objection. His statement produced something like dismay in the osteopathic ranks, a result which I submit amply justified my motion. The best means, in my opinion, of finally defeating the osteopathic movement would be to institute a diploma in manipulative surgery similar to those now in force in ophthalmology, laryngology, and tropical medicine; and the courageous statement of the Minister that qualified medical men are no longer neglecting manipulative surgery should encourage the institution of such a diploma.

The position of the Parliamentary Medical Committee should, I think, be made clear to the profession. It consists of all members of Parliament who happen to be qualified medical men, together with certain representatives (not themselves medical men) of universities with large medical constituencies. We have been elected to Parliament for political, not professional, reasons. With the exception of the university members, none of the committee can be said to represent medical opinion in any particular way—the chairman, for instance, sits for an agricultural constituency; four-fifths of the committee have either never practised or do not now practise. My position in that committee is somewhat exceptional, inasmuch as I remain in full and active practice—both hospital and private—and I am the only member who holds an appointment on the staff of a medical school in London or who has had continuous experience of medical education in the metropolis for thirty years. This position, of course, has its obvious drawbacks. I cannot speak with the detachment of the retired practitioner. But I claim that the position has more than corresponding advantages, inasmuch as I am in close touch with current opinion at the great medical schools and the great medical societies of London. I believe that I voiced this opinion in my motion of February 9th.—I am, etc.,

London, W., Feb. 16th.

E. GRAHAM LITTLE.

** We refer to the main subject of Dr. Graham Little's letter in a leading article at page 337.

THE STATISTICAL STUDY OF CANCER.

SIR,—I greatly regret if anything I have written has given offence to Dr. Greenwood or his colleagues on the Statistical Committee instituted by the League of Nations. Though not a statistician, I think I can appreciate the enormous labour and the great care which have gone into the making of their report. I hoped that I had given in my lecture full expression to my admiration for their work, and I cannot help thinking that Dr. Greenwood has read into my remarks a meaning which was not intended by me. In order to give a survey of our present knowledge of cancer in the narrow limits of one lecture I had necessarily to be brief in dealing with the various aspects. I do not see, however—even after reading carefully Dr. Greenwood's letter—where I have been guilty of a misstatement; and the last sentence of Dr. Greenwood's letter makes me doubt whether he has correctly appreciated the point which I raised. It should not be necessary for me to say that I had no intention of disparaging either the results or the mentality of cancer statisticians. I merely wished to show how completely the new conception of cancer affects the investigation of cancer in all its branches. I can assure Dr. Greenwood that there are several facts in experimental cancer research which have been overlooked by all of us because we did not have the knowledge to interpret them correctly, and to appreciate their significance. I am not a statistician and I do not presume to argue with Dr. Greenwood on questions of statistics, as such. But I submit that statistics on cancer are not a purely statistical problem, that they are subject to pathological considerations, and that the following considerations are relevant.

Until quite recently the development of cancer in a

particular organ or tissue was regarded as the result of a purely local process unconditioned by general factors involving the organism as a whole. From this point of view cancer of a particular organ or tissue could be regarded as a separate entity. It was natural to assume that differences in the incidence of cancer of the breast in different countries could be correlated with local conditions of the affected organ. So far the results of this very statistical investigation have failed to reveal any such correlation.

But since the statistical inquiry was instituted a complete change has come over our conception of cancer. There is new experimental evidence that the local process which leads to the development of cancer is conditioned by general factors. I gave as an instance in my lecture that a resistance to the induction of skin cancer by tar is, according to Murray, established by the previous genesis of cancer in some other organ—the mamma, for instance. The reverse is also true. Mammary cancer is relatively frequent in mice. In this laboratory we have had under observation during the last five years certainly over 200 mice with skin cancer induced by tar, in which the tumour was removed by operation so that the animals could reach what is for a mouse a ripe old age. Only one case of mammary carcinoma has occurred in these mice. In this group of mice the incidence of mammary cancer has been diminished by the increased incidence of skin cancer.

In addition to observations of this kind, we have the discovery of Gye which shows that all cases of cancer have in common one extrinsic factor—the virus. This also is a general and not a local factor.

It seems to me to follow clearly from experimental observations such as these, that we can no longer discuss the incidence of cancer in one particular organ as a self-contained phenomenon. We can no longer look upon the total mortality from cancer as merely the sum total of the mortality from cancer of the individual organs. We now have to recognize that there are not only local but also general factors determining the incidence of cancer in any particular organ or tissue.—I am, etc.,

Imperial Cancer Research Fund,
London, W.C.1, Feb. 16th.

W. CRAMER.

THE ULTRAMICROSCOPE IN CANCER RESEARCH.

SIR,—I have to thank Mr. Barnard for his reply (February 6th, p. 260) to my letter of January 16th, 1926 (p. 119), with its misleading and irrelevant matter. This latter, I can assure him, is not due to careless reading of his or of other publications, but simply to my being what in Scotland we call "slow in the uptake," so that it is my intelligence that is at fault, not my hurried reading.

My use of the term "ultramicroscope" may not, in Mr. Barnard's opinion, be correct, but what he says in his letter in no way indicates that it is not descriptive of the work he has done. Mr. Barnard implies that no x rays have been used in any way in his work, but he is well aware that in the now recognized spectrum of rays there is a gap between the ultra-violet and the x rays, and that the nature of the rays therein contained has not yet been cleared up. What this unknown series contains is problematical, but in this unknown gap there may be some rays closely allied to the x rays, if not identical with them in their action. In fact, in this supra-ultra-violet ray gap there may be radiations that have a special influence on growth, as well as on human life. Mr. Barnard's letter shows that he is not absolutely certain about the causation of the results he has obtained, and he is finding it necessary to continue investigations in which x rays are to be used. It will be interesting to hear what results come from the inquiry that he says is now in progress. When one is dealing with invisible rays and considers how little is certainly known about their biological action on tissues, any opinion as to their method of action scarcely merits the term "misleading."—I am, etc.,

Glasgow, Feb. 16th.

GEORGE THOMAS BEATSON.

COCCIDIA OF FISH IN HUMAN FAECES.

SIR,—The very interesting communication by Thomson and Robertson which appeared in your last issue (February 13th, p. 282) has solved a difficulty which has for some time been apparent to me. The three coccidia *Eimeria wenyoni*, *Eimeria oxyspora*, and *Eimeria snijdersi*, which Dobell and others regarded as parasites of man, have now been shown to be common parasites of the liver and "soft roe" of herrings, and there can be no doubt that the cysts which appeared in human faeces were merely passing through the human intestine and were no indication that the human beings were parasitized. The cysts, as in the first case which was described by me in 1916, were present in the stools for a very short time only, and it is remarkable that the true explanation of their presence should have so long escaped notice. I myself (1916) did, however, suggest that the one seen by me might have been *Eimeria falciformis* of mice. Dobell and others who followed him concluded that the cysts belonged to parasites specific for man, though Brug (1922) suggested that the form seen by Snijders (1921) in the faeces of a patient in the Dutch East Indies, and named *Eimeria snijdersi* by Dobell, was possibly not a human parasite at all but one which had been eaten with food. Brug points out that natives of Eastern countries often eat the intestines and livers of animals, a fact which may explain the temporary occasional presence of unusual cysts in the stools. He even went so far as to make the suggestion that the degenerate condition of many of the cysts, which was a feature of this particular case, might be accounted for by the heating used in the preparation of the food.

I have for some time been aware of the fact that the coccidia described by Thélohan (*Eimeria clupearum* and *Eimeria sardinac*) corresponded morphologically with Dobell's *Eimeria wenyoni* and *Eimeria oxyspora*, and, as I pointed out to Dr. Thomson, I had already stated in the manuscript of my forthcoming book on protozoology that it was very probable that the supposed parasites of man were merely coccidia of fish, as Thomson and Robertson have now demonstrated.—I am, etc.,

London, W.C.1, Feb. 12th.

Wellcome Bureau of Scientific Research.

BLOOD PRESSURE IN THE SCHOOL CHILD.

SIR,—I have followed with interest Lord Dawson's arguments (BRITISH MEDICAL JOURNAL, 1925, ii, p. 1161) in favour of school medical officers devoting some special attention to blood pressure readings in school children, and have read with equal interest Dr. Stocks's letter on the subject (ibid., p. 1244). After mature consideration, however, I regret that I cannot agree either with their premises or with their conclusions. Since 1911 I have taken blood pressure in all boys as a routine measure, but I have long ago discarded the assumption that such readings have the slightest clinical or theoretical value. When I became medical inspector of schools in the Transvaal in 1914, and found that my readings leaped up in an alarming fashion with differences of altitude, humidity, and temperature, I thought it time to devote a little more attention to blood pressure in general, and after such study I cannot say that I am at all convinced that in present circumstances "blood pressure readings" are of any real value. We use the term "blood pressure" in such widely different ways; so far as I can follow, Lord Dawson, in his address at Bath, gives it three entirely different meanings, and if a hydraulic engineer were to discuss the subject he would probably differ widely from the interpretations attached to each. Nor do I like the term "hyperpiesis" any better; apart altogether from its etymological absurdity, it conveys no further information than the term, as generally used, "high blood pressure."

My records of blood pressure estimation in Transvaal school children, especially in those with chronic malarial cachexia, number more than 12,000, so I may claim to be able to speak with some authority. Moreover these are both systolic and diastolic readings, and personally I attach no importance whatever to a single systolic record, unconfirmed by readings taken, with all due allowance made

for psychical influences that can, however, never be entirely excluded and that may seriously affect the systolic readings, after exercise and in both the sitting and recumbent positions. Such readings take up a great deal of time, and cannot possibly be carried out at routine examinations, though they can, and ought to be, attempted at the examination clinic.

Notwithstanding my voluminous record cards, I am more than chary of attempting to draw conclusions. I did attempt to do so in regard to the blood pressure of malarious children, and published my conclusions in the *South African Medical Journal*. I then thought that the changes in blood pressure, especially in the diastolic readings, in such children might throw some light upon the "debris" theory of cortical emboli in that disease and explain some of the post-malarial psychoses in children. With wider experience I no longer hold that view, for it seems to me that it is purposeless to try and measure intra-arterial pressure in brain or cord by arm or leg readings in which, for really scientific purposes, a great many factors other than arterial pressure or tone have to be taken into consideration. Nor do extraordinarily wide excursions of the manometer give us much better insight into the physiological action of the vascular system. I have followed up most of my high and low readings, and the data are of little value one way or the other. I have not found a single boy who had what one might call an abnormally high pressure—I am not yet sure what is a normal pressure for, say, 90° F., 500 feet altitude, average humidity, and average actinic influence—without presenting other abnormalities that were of greater clinical importance; herein my experience obviously differs from that of Dr. Stocks. I have lately examined two boys, one of 9 and one of 11, sent to me simply because the family doctor thinks, from clinical examination, that they have a high blood pressure, but cannot find any symptoms. Both are suffering from a definite intoxication. One boy, whose pressure formula is recorded as " $\frac{135}{85}$; 72; 82, regular, bounding, normal wall," has fairly extensive caries of the teeth, with probably antral trouble. The 9-year-old (" $\frac{134}{84}$; 55; 102; easily compressible, regular") had irregular attacks of fever some months ago, and his urine gives a positive Griess-Hosvay reaction, so I have no doubt that, upon plating, it will be found that he is suffering from a chronic coli pyelitis. Some of the highest pressures, diastolic as well as systolic, recorded in my notes concern children who are of the well known Stiller type, with probable enteroptosis, and at all events a decided dys-equilibrium in general muscle tone.

I may carry the attack into, let me not say the enemy's territory, but the other extreme domain, by suggesting that cases of early hypotension will repay following up. Indeed, I consider a distinctly low diastolic pressure in childhood, especially when there is a loss or weakening of the ankle reflex, of some clinical significance. I cannot say that the moderately high pressures recorded have so far yielded data of any great clinical value—I allude to those in which there were obviously no other recorded signs of pathological abnormality. Naturally all have not been followed up, but those that have been seen again, some after six and others after ten years, show no signs of arterial degeneration and do not even show a trace of postural albuminuria.

I write, not to discourage school medical inspectors from recording pressures, but simply to state that such readings have already been largely done without yielding those significant results that Lord Dawson adumbrates. So long as our concepts of blood pressure, and our terms in relation to it, are as unscientific and as inchoate as they appear to be at present, no definite results can be looked for. I would suggest that a representative medical committee be appointed to consider the whole question of blood pressure and the hydraulics of the circulation. Such a committee, especially if it secures the help of competent physicists, should be able to clarify much of the present muddle, both in regard to terminology and definition, and to the interpretation of data. Perhaps Lord Dawson and Dr. Stocks might take the initiative in this much-needed reform.—I am, etc.,

Capetown, Jan. 22nd.

C. LOUIS LEIPOLDT.

SPENCER'S "CAESAREAN SECTION."

SIR,—Your reviewer of Dr. Herbert Spencer's book made a serious error in the figures he quoted, presumably in support of Potter. He recognized his error, but would have been more likely to overtake his mistakes if he had given in his correction actual and correct statistics in the interesting comparisons he drew attention to, instead of making probable statements. It is difficult to see how by any basis he reduces the Edinburgh figure to 8 per 1,000, or even the Manchester figure to 36. Still, the true figures which I shall give place Potter in a very lurid light. He further suggests that Spencer reduces his number of sections by doing induction as an alternative. Spencer quoted Rotunda figures for sections as comparable with his own, but figures for induction in the Rotunda are not shown.

I have taken the following figures from the same reports as those to which your reviewer referred. The total number of cases is composed, in each instance, of intern deliveries, excluding abortions and early miscarriages, except for Liverpool and University College, London, plus the deliveries in the districts; this latter does not exclude abortions.

Hospitals.	Total Cases.	Caesarean Sections.	Induction.	Cranio-tomy.	Total C. P. Cases.
University College ...	5,647	All 37	C. P. 32	C. P. 113	2
Per 1,000 ...		6.5	5.6	20	0.4
Edinburgh ...	2,086	54	31	24	11
Per 1,000 ...		25	15	11	5.4
Manchester ...	2,581	138	116	12	15
Per 1,000 ...		53	45	5	5.8
Liverpool... ..	2,269	93	88	117	5
Per 1,000 ...		40	38	51	2.2
Sheffield ...	968	41	37	2	16
Per 1,000 ...		42	38	2	16
Rotunda ...	3,636	19	19	12	1
Per 1,000 ...		5.2	5.2	4.4	0.3
					33* 9

C. P. = Contracted pelvis.

* Includes one pubiotomy.

It is interesting to compare the following figures, from Manchester and the Rotunda Hospital for the year 1910, with those given above.

	Manchester.	Rotunda.
Total cases ...	4,388	4,406
Caesarean sections—		
All ...	25	4
Contracted pelvis ...	22	4
Induction (contracted pelvis) ...	17	6
Craniotomy (contracted pelvis) ...	14	2
Total contracted pelvis cases ...	55*	16†

* Includes 2 pubiotomies.

† Includes 4 pubiotomies.

The year 1910 was that immediately preceding Routh's paper, which had an enormous influence in stimulating the performance of Caesarean section early in or before labour.

I do not propose to defend the number of inductions in University College, but I would wish to point out that it is a relatively much safer operation than section. In Queen Charlotte's Hospital during six years induction was performed 346 times with one death, and section was done 203 times with four deaths, the latter giving six times greater mortality than the former. It is inconceivable that the physique of the female population has degenerated to the extent suggested by operative obstetrics. Perhaps the explanation is suggested by your reviewer when he refers to Spencer's longer experience and greater faith in the natural processes of labour. Spencer learnt his obstetrics at a time when the dangers of surgery were great, and it was only resorted to when Nature failed; whereas the present-day obstetric surgeon, being impressed by the comparative safety of surgery, resorts to it as a substitute for obstetrics, overlooking the incomparably greater safety of the natural process, and thus fails to appreciate the wonders of which Nature is capable. Spencer's book seems to be a timely call of "Halt" to the excessive vogue of section.—I am, etc.,

Rotunda Hospital, Feb. 9th.

GIBBON FITZGIBBON.

THE ACTION OF PITUITARY EXTRACT ADMINISTERED BY THE ALIMENTARY CANAL.

SIR,—In your issue of February 6th (p. 234) Dr. Knaus made a valuable communication on the efficacy of pituitary extract administered by the mouth in promoting uterine contractions. In his paper he made certain criticisms of my original experiments which appear to be based on a misunderstanding, possibly due to the somewhat condensed form in which the communication was published (*Proceedings of the Royal Society of Medicine (Therapeutics Section)*, 17, 1921).

He writes: (1) "The method of recording uterine movements was such that any small movements of the animal upset the record . . ." and (2) "He states himself that the records were difficult to obtain on account of peristalsis and straining." Precaution was taken in my work to avoid straining by having the animals deeply anaesthetized, and it was rare for it to occur within an hour after the administration of the pituitary extract, whereas uterine contractions set in usually within ten minutes to half an hour. Any experiments where movement or straining occurred before the onset of well marked uterine contractions were discarded. The second quotation, it will be seen on reference to the original paper, refers to experiments on absorption from the intestine; no conclusions were drawn from them.

My observations showed that absorption from the stomach was most rapid in animals recently fed. It would be interesting to know whether Dr. Knaus repeated this observation.

I am interested to see that Dr. Knaus confirms my observation that no effect on blood pressure was demonstrable.—I am, etc.,

London, W.1, Feb. 15th.

P. HAMILL.

TETANUS FOLLOWING OPERATIONS FOR
HÆMORRHOIDS.

SIR,—Your correspondent Dr. Andrew Smith, in your issue of November 28th, 1925 (p. 1031), asks for the experience of others on this subject. We have got to thank Dr. Smith for his courage in publishing the case.

I know of four cases in which tetanus followed ligature of a pile—all in the hands of careful men; one of them was in my own hospital, done by my assistant. On his arrival I drew his attention to the other three cases, and pointed out to him that they were all explicable by Colonel Semple's investigations on the relation of quinine administered intramuscularly being followed by tetanus occasionally. He had done hundreds of such ligatures, and had no accidents. I was out in camp shortly after, and on my return I found a case of tetanus in hospital following a ligature of a pile by him. He was then more easily persuaded to desist from ligaturing piles.

On this subject I would invite attention to Colonel Semple's paper in the *Scientific Memoirs of the Government of India*.—I am, etc.,

HENRY SMITH, C.I.E.,
Lieut.-Colonel I.M.S. (ret.).

January 26th.

NOVASUROL.

SIR,—I notice from recent literature that the diuretic novasurol is coming into prominence. I believe I was the first in this country to give it notice in page 96 of my book *Modern Aspects of Syphilis*, published in January, 1923, where it is referred to as a powerful diuretic.

I beg to endorse the note in the *JOURNAL* of February 6th (p. 261) by Professor Moorhead as to the advantage of commencing with small doses. On the other hand, perhaps my experience of several thousand intravenous injections of 1.5 to 2 c.cm. may be of interest.

For an average male adult I use 1.5 to 2 c.cm. of novasurol combined with, say, 0.45 gram neosalvarsan dissolved in 8 c.cm. aq. dest. in weekly doses, sometimes every fifth day. The mixture alters somewhat in colour. No evil effects were noted by the patient; certainly no day's work was lost.

In non-syphilitic diseases this mercurial is not borne so well. I have given several hundred injections in general medical cases where its use seemed indicated, in weekly doses of 1.5 to 2 c.cm., intravenously. Effects alarming enough ensued very often—ulcerated mouth, profuse diarrhoea, bloody stools. Yet some of the moribund water-logged cases on which this remedy was tried rallied in surprising fashion. In the cases in which I was driven to control this mercurial intoxication by injections of contramine, I found the diuretic effect continue as powerfully as in those cases which were left uncontrolled. Latterly in debilitated cases I have given an injection of contramine before or very soon after the injection of novasurol, and have still noticed the diuresis, whereas enteritis and sore gums were absent.—I am, etc.,

Nottingham, Feb. 8th.

M. J. HORGAN.

INDIVIDUAL OVERDOSE OF ULTRA-VIOLET RAYS.

SIR,—I have read with interest Dr. Paige Arnold's letter on individual overdose of ultra-violet rays in your issue of February 13th (p. 304). I have administered ultra-violet ray treatment by means of a "Percy Hall" lamp extensively in my practice during the last year for many and varied diseases, and have not yet come across a single patient who demonstrated the severe group of symptoms which he has enumerated. I have treated eczemas of the scalp and alopecia, and have pushed the treatment in the former disease to as much as fifty minutes at a distance of six inches. Bodily irradiation has been given up to half an hour at twelve inches for conditions such as hyperpiesis, anaemia, etc.

Dr. Percy Hall refers in his book to two cases of "idiosyncrasy" to the treatment, when in each case severe symptoms resulted after an irradiation lasting only two minutes.

Dr. Paige Arnold refers to the similarity in the symptoms caused by large doses of ultra-violet rays and α rays. But no doubt he is aware of the entirely dissimilar biological and physiological effects of the two forms of treatment. We know that α rays produce an endarteritis of the capillaries, whereas ultra-violet rays produce a dilatation. α rays kill the hair follicle, whereas ultra-violet rays stimulate the hair follicle—hence the good results in alopecia, and the obvious advantages of ultra-violet ray treatment over α -ray treatment in such conditions as ring-worm of the scalp. α -ray treatment causes a leucopenia, whereas a leucocytosis is produced by ultra-violet ray treatment.

No doubt an occasional patient—and this one must be a very small percentage of the total treated—will show an idiosyncrasy. Perhaps I have been lucky, but undoubtedly Dr. Paige Arnold has been the reverse. In my opinion, and after one year's experience, this is a form of treatment which no practitioner can afford to neglect.—I am, etc.,

W. A. TROUP, M.C., M.B., Ch.B.

Cooden Beach, Sussex, Feb. 13th.

SIR,—May I be allowed to endorse the warning uttered by Dr. Paige Arnold as to the dangers of indiscriminate dosage of ultra-violet rays in your issue of February 13th (p. 304)?

I have uttered similar warnings time after time during the last two years, both written and oral, pointing out the dangers to patients if this remedy is administered by unskilled or inexperienced operators, and particularly if left to unqualified persons. Instances of medical men referring both children and adults suffering from tuberculosis and other diseases to lay operators, with no indications as to dosage and no supervision save of the most perfunctory character, reach me from time to time. Quite apart from the questionable ethics of this procedure is the actual danger to the well-being, and, indeed, occasionally lives, of these patients.

Ill results thus occurring are likely to bring into undeserved disrepute and discredit one of the most valuable therapeutic remedies at our disposal. The dosage given is

frequently too great, too frequently repeated, and at too short intervals. The heresy of the necessity of brisk erythematata followed by pigmentation is to blame for these mistakes.

The comparison between the effects of ultra-violet and α rays can be carried too far. One does not wish to frighten either the profession or the public, and it is tolerably certain that ultra-violet irradiation is not likely to be followed by any remote ill effects such as has happened after the use of α rays. Certainly no ill effects have ever been described following the intensive and long-continued local irradiation of lupus by the Finsen lamp, although the records go back over a quarter of a century.

I uttered warnings of this character throughout the text of my book on *Ultra-Violet Rays*, and especially in the preface to the second edition.—I am, etc.,

London, W.1, Feb. 15th.

PERCY HALL.

ETYMOLOGY OF "ORTHOPAEDICS."

SIR,—I suppose that there are few medical terms of which the etymology is more certain, and few of which it is more often questioned, than "orthopaedia," "orthopaedic," etc. The question crops up, is answered apparently with finality, and is asked again every few years. This has been going on ever since orthopaedic surgery was revived in this country, about ninety years ago.

In the preface to "Orthopaedia: or the Art of Correcting and Preventing Deformities in Children, etc., Translated from the French of M. Andry, Professor of Medicine in the Royal College, and Senior Dean of the Faculty of Physick at Paris," etc., published in London MDCCLXIII, you will find the following, which is a faithful translation of the original French:

"As to the Title, I have formed it of two Greek Words, viz. *ὀρθός*, which signifies straight, free from Deformity, and *παῖδιον*, a Child. Out of these two Words I have compounded that of Orthopaedia, to express in one Term the Design I propose, which is to teach the different Methods of preventing and correcting the Deformities of Children. The Expression seemed to me the more allowable, that the two celebrated Authors above cited, [he refers to Scévole de Sainte Marthe and Claude Quillet] have made use of Terms of the same Kind; the first in giving the Title of Paedotrophia to a Treatise upon the Manner of suckling Infants; and the second that of Callipaedia, to a Poem upon the method of getting beautiful Children: both which Titles are likewise taken from the Greek; the first from *παῖς* an Infant and *τροφή* Nourishment; and the second from *καλός* beautiful, and *παῖδιον* a Child."

In the face of this very explicit statement it would seem that speculations about *παίδεια*, etc., are superfluous, and confuse the modern meaning of the term with its etymology. May I suggest that it might save future trouble if you were to have the above passage from Andry's book printed on a leaflet for the information of future critics of "orthopaedic," who are sure to turn up before long?—I am, etc.,

London, W.1, Feb. 12th.

E. MUIRHEAD LITTLE.

SIR,—Your derivation of the word "orthopaedics," in the footnote to Dr. Mackay's letter, is of course correct. But none of the standard dictionaries gives the historical origin, although examples of its use in literature are quoted in the *New English Dictionary*. I wrote an account of the birth of the word in an article which appeared in the *BRITISH MEDICAL JOURNAL* of August 11th, 1917. It was first coined in 1741 by M. Andry, Professor of Medicine in the Royal College, and Senior Dean of the Faculty of Physick at Paris. He wrote a book to which he gave the name "Orthopaedia," and explains his choice of the title as follows: "I have formed it of two Greek Words, viz. *ὀρθός*, which signifies straight, free from Deformity, and *παῖδιον*, a Child. Out of these two Words I have compounded that of Orthopaedia, to express in one Term the Design I propose, which is to teach the different Methods of preventing and correcting the Deformities of Children." Although Andry had the straightening of children primarily in mind, yet the meaning of the word

has gradually been extended so as to denote the prevention and correction of deformity, from whatever cause, in children and adults.

The practical difficulty of the word "orthopaedic" has rarely been with reference to the shades of Greek meaning, but rather in the assumption of a Graeco-Latin derivation. This is a common mistake even of the informed public, leading them to regard orthopaedic surgery as being concerned with disabilities of the foot only, and they are not helped when we choose to write "orthopedic" instead of "orthopaedic."—I am, etc.,

ARTHUR ROCYN JONES, F.R.C.S.

London, W.1, Feb. 15th.

SIR,—As regards the etymology of "orthopaedics," may I point out (1) that if it were derived from *ὀρθός* and *παῖς* the word would be either "orthopaedeutics" or "orthopaedeusis"; (2) that the word primarily refers to putting children straight? The fact that grown-up people occasionally were not put straight as children does not necessarily render childish, even though etymologically correct, the use which most of us (who had possibly never seen the word *παῖς*) had made of the word—that is, referring primarily to children. To recapitulate, the Greek verb *παίδεω* could not correctly make an ending "-paedics."—I am, etc.,

Flackwell Heath, Bucks, Feb. 13th.

G. D. PARKER.

** We wish to thank other contributors to this discussion for letters the substance of which is contained in the communications of Mr. Muirhead Little and Mr. Rocyn Jones.

THE FINAL NURSING EXAMINATION.

SIR,—I am very glad to see Dr. Bradley's letter in the present issue of the JOURNAL (February 13th, p. 305) calling attention to the absurd questions asked the nurses in the medicine examination paper.

In the JOURNAL two years ago (February 23rd, 1924, p. 354) I, with others, strongly protested against the time of the nurses being taken up by instruction in medicine and surgery, the knowledge of which would be of no use to them as nurses. I said, "On no account would I advocate the lowering of the standard of nursing knowledge," but I pointed out that they were being trained as if they were going to practise as doctors rather than nurses. Would it be possible to find a more glaring instance of this than the examination paper to which Dr. Bradley has called attention? It might very well have been set for a final examination for medical students. How much more capable is a nurse—as a nurse—because she knows the early symptoms of typhoid fever? There would be some sense in the question if she had been asked what symptoms might indicate perforation of a typhoid ulcer; every nurse ought to know that, so that she may at once summon the doctor; or what characters she should be on the look-out for in the motions.

Then take Question 2. Why should any nurse be expected to differentiate between gastric ulcer and other abdominal diseases? In the next paper in medicine the nurse will probably be asked the skiagraphic appearance of gastric ulcer, and what variety of tube the x-ray examination should be made with. The diagnosis of gastric ulcer is an endless source of mistakes to doctors, and how can a nurse be expected to have any clear idea about it, and why should she? If she thinks she can diagnose it, such an idea may do actual harm, for she may be so unwise as to hint to some patient she suspects its presence, and unnecessarily alarm him.

With regard to Question 3, may I ask: Are nurses who pass the General Nursing Council examination to consider themselves qualified to treat retroversion of the uterus, and, if not, why are they expected to answer such a question?

As Dr. Bradley truly says, if nurses have to waste their time getting up such information many will abstain from joining the nursing profession. Is it for instruction in such matters they pay fees which support sister tutors? I suspect that the reasons such absurd questions have been asked in this medicine paper is because some lecturers in

medicine to the nurses have been lecturing to them as if they were medical students, and the paper was set by some of these lecturers, and what they have been teaching them in the lectures they thought they could fairly examine them on. The initial mistake is therefore in the lecturer taking them over ground which is quite beyond the scope of a nurse's training.

I say again they cannot be too highly trained as nurses, but this is not nurses' training; it is training them to be doctors and rendering them, not more valuable as nurses, but even dangerous; for they may use this useless knowledge actually to the detriment of the patient.—I am, etc.,

Bristol, Feb. 14th.

CHARLES A. MORTON.

The Services.

MILITARY HOSPITALS RESERVE.

The reorganization of the Home Hospitals Reserve under the designation of "The Military Hospitals Reserve" has been approved, and the qualifications for enrolment are stated in an Army Order issued on February 14th. This Reserve will consist of warrant and non-commissioned officers and privates only, with an authorized establishment of 2,000. The functions of the Reserve will be (a) to staff the military hospitals and other establishments maintained by the regular medical services upon the mobilization and withdrawal of the regular R.A.M.C. for duty in the field; and (b) to provide reinforcements for the medical units of the expeditionary force overseas after mobilization.

Membership will be entirely voluntary, and the personnel will be provided by the St. John Ambulance Brigade for England and Wales and Northern Ireland, and the St. Andrew's Ambulance Corps for Scotland.

The age limits for enrolment will be from 19 to 40, and no member will be permitted to remain in the Reserve after he has reached the age of 45. Every applicant must be in possession of the first-aid certificate recognized or granted by the St. John Ambulance Association or St. Andrew's Ambulance Association, and obtain a nursing certificate recognized by those bodies within a period of twelve months after enrolment. A proportion of the total establishment of each rank in the Reserve will, in annual rotation, receive training for eight days in a military hospital or other military medical establishment, and as far as possible each member will be sent to the hospital to which he would be posted on mobilization. A member of the Reserve will receive, both during training and on coming up for duty in replacement of a member of the R.A.M.C., pay and allowances at the rates laid down for a man of the corresponding army rank and trade group (if qualified) whom he replaces on mobilization; promotion to fill the authorized establishment of ranks during service in the Reserve will be given according to service, merit, and qualifications.

DEATHS IN THE SERVICES.

Lieut.-Colonel Augustus Edward Richard Stephens, Bengal Medical Service (ret.), died in London on January 29th, aged 75. He was born on October 24th, 1850, the youngest son of the late Matthew Spray Stephens, solicitor, of Gillingham, and was educated at Charing Cross Hospital, taking the M.R.C.S. in 1873 and the L.R.C.P. Lond. in 1874. Entering the I.M.S. as surgeon on March 31st, 1876, he became surgeon lieutenant-colonel after twenty years' service, retiring on April 25th, 1897. Most of his service was spent in military employ, but for the last few years he was in civil employ in Bengal. He served in the Afghan war of 1878-80, when he was present at the battle of Ahmed Khel, and received the medal with a clasp; and on the North-West frontier of India in the Hazara expedition of 1883, receiving the frontier medal with a clasp.

Lieut.-Colonel William Woppell Pope, C.M.G., R.A.M.C. (ret.), died at Bournemouth on January 31st, aged 68. He was born at Exeter on September 17th, 1857, the son of John Pope, of Baring Lodge, Exeter, educated at Sherborne, and, after taking the M.R.C.S. and L.R.C.P. Ed. in 1880, entered the army as surgeon on February 5th, 1881. He became lieutenant-colonel after twenty years' service, and retired on June 22nd, 1901. He had a long list of war service—Egypt, 1882, battle of Tel-el-Kehir, medal with clasp and Khedive's bronze star; South Africa, Bechuanaland campaign, 1884-85, and operations in Zululand, 1888; north-west frontier of India, 1897-98, Tirah, medal with clasp; South Africa, 1899-1900, operations in Natal, actions at Reitfontein and Lombard's Kop, defence of Ladysmith, Queen's medal with a clasp. On October 1st, 1914, he rejoined for service in the recent great war, and in 1917 received the C.M.G. In 1917 he married Mabel Jennie, only child of George Whitwell of Durham.

Obituary.

HENRY RAYNER, M.D., M.R.C.P.Ed.,

Formerly Physician for Mental Diseases, St. Thomas's Hospital.

WE regret to record the death of Dr. Henry Rayner on February 8th, at the age of 84. He was the son of Mr. W. Rayner, J.P., of Hythe, Kent, and received his medical education at St. Thomas's Hospital and the University of Aberdeen. During his student days in London he took an active interest in philanthropic work, and was associated with the Bermondsey Social Mission, then under the Bishop of London's Fund. He was also president in 1863-64 of the London Medical Students' Union, also known as the Junior Medical Society of London. In 1864 he obtained the diplomas M.R.C.S.Eng. and L.S.A., and graduated in 1866 M.B., C.M.Aberd. with highest honours, proceeding M.D. in 1870. In 1878 he became a member of the Royal College of Physicians of Edinburgh.

After serving as resident assistant physician at Bethlem Royal Hospital Dr. Rayner decided to specialize in psychological medicine, and was appointed out-patient physician for mental diseases, and lecturer in this subject, at St. Thomas's Hospital, where the organization of the mental clinic nearly fifty years ago was mainly due to him. He was also for some time lecturer on mental diseases in the Middlesex Hospital school, and for several years he held the responsible post of medical superintendent of the male department of the London County Council Asylum at Hanwell. During the war he acted as consulting physician to the "Recuperative Homes" at Hampstead, established by Sir Frederick Milner for ex-service men suffering from nerve diseases. In 1870 Dr. Rayner became a member of the Medico-Psychological Association of Great Britain and Ireland; he was elected general secretary in 1877 and president in 1884. He was co-editor of the *Journal of Mental Science* from 1895 to 1911. His literary contributions to psychological medicine were very numerous and varied; they include an article on "Melancholia and hypochondriasis" in *Allbutt's System of Medicine*, on "Sleep and narcosis" in the *Journal of Mental Science* (1902), "Early treatment of mental defects in children," "Gout and insanity," and "Moral insanity."

At the Annual Meetings of the British Medical Association in 1879, in 1892, and again in 1895, Dr. Rayner was vice-president of the Section of Psychology. At the Annual Meeting at Carlisle in 1886 he read a paper on incipient insanity, which led to the appointment of a joint committee of the Association and of the Medico-Psychological Association, of which he was appointed chairman. Suggestions were made by this committee to the Lord Chancellor and resulted in amendments of the Lunacy Acts during the three succeeding years. For more than a quarter of a century he was chairman of the council of the Mental After-Care Association, for poor persons convalescent or recovered from institutions for the insane, which has rendered most valuable assistance by enabling a large number of convalescent mental patients to take up again active life in the community without relapsing.

Dr. Rayner was deeply interested in horticulture, and his family residence at Hythe, in Kent, is noted for its gardens. He was a sturdy pedestrian, and in his younger days possessed considerable golfing abilities.

M. W. B. OLIVER, M.A., M.B., F.R.C.S.,

Surgeon, Central London Ophthalmic Hospital.

THE news of the premature death of Mr. M. W. B. Oliver will be received with profound regret by a large circle of friends and contemporaries. He was playing golf, and apparently in good health, on February 6th, and died from pneumonia at his sister's house in the country on February 10th.

Matthew William Baillie Oliver was born in 1832; his father was the late Robert Oliver of Strathwell, Whitwell, Isle of Wight. He was a descendant of the famous morbid anatomist and physician to

St. George's Hospital, Matthew Baillie, M.D., F.R.S., whose mother, Dorothea Baillie, was a sister of the great anatomists, John and William Hunter, and whose sister was Joanna Baillie, the poetess. From Cheltenham College Matthew Oliver went to Trinity, Cambridge, and graduated B.A. in the Natural Sciences Tripos of 1903. He then entered St. Bartholomew's Hospital, and after obtaining the M.R.C.S. and L.R.C.P. diplomas in 1906 served as ophthalmic house-surgeon. He next held resident house appointments at St. George's Hospital for two years, and in 1909 proceeded to the M.A., M.B., and B.Ch. degrees. While at St. George's he used his spare afternoons to work as a clinical assistant at the Royal Westminster Ophthalmic Hospital, and later became chief assistant in the eye department at St. Bartholomew's and at Moorfields. In 1914 he obtained the F.R.C.S.Eng. diploma, and was appointed assistant ophthalmic surgeon to the Miller Hospital, Greenwich. Subsequently he became surgeon to the Central London Ophthalmic Hospital, ophthalmic surgeon to the Royal National Orthopaedic Hospital, to Queen Mary's Auxiliary Hospital at Roehampton, and to the Italian Hospital; and consulting ophthalmic surgeon to the Willesden Urban District Council. At the Central London in particular, where much of his work was done, he will be sadly missed. During the Annual Meeting of the British Medical Association at Portsmouth in 1923 he was honorary secretary of the Ophthalmological Section.

This bare record will reveal Oliver's energy and capacity for work, and it was the same for games. At St. Bartholomew's, for instance, he was one of the keenest and hardest working forwards in the Rugby football fifteen. He confessed to having overstrained his heart at games, and possibly this may have turned the scale against him when he succumbed in a few days to pneumonia. Such a character must have been the life and soul of any mess to which he chanced to be attached during the war, and his work in France, where he was surgical specialist to No. 15 Casualty Clearing Station and held the temporary rank of Major R.A.M.C., met with approval from the highest authorities. He was mentioned in dispatches and received the O.B.E. On returning in 1919 he did much useful plastic work at the Queen's Hospital at Sidcup. The region of the orbit and eyelids was allotted to him, and this was one of the few subjects on which he wrote. Here a knowledge of general surgery, combined with ophthalmology, was invaluable. If he never accomplished anything very original he did an enormous amount of careful and thorough work in a department where such qualities count for more than show and brilliance.

His singularly happy nature endeared him to all who had the good fortune to be associated with him, and the writer, who knew him at school, at the university, at hospital, and later on during the war in France and at Sidcup, and in later days met him not infrequently in practice, never remembers him except as cheerful and smiling. One day at the end of the morning in his consulting room Oliver had just made the discovery that the last patient had not only spilt the ink on his new carpet, but had forgotten to add his signature to the cheque; even this combination of injuries left him quite unruffled. He was known to all his friends without exception as "Bubbles." Whatever the origin of this was, it seems to indicate that happy, friendly, fearless soul, always bubbling with energy and life. It is by that name that he will long be remembered.

L. C.

From two other close friends we have received the following tribute: The sudden and quite unexpected death of M. W. B. Oliver came as a shock to his many friends. Wherever Oliver found himself he made friends; and it can truly be said that he did not have an enemy. This was due partly to his cheerful optimism and in part to his unflinching sympathy with all classes with which he came in contact. His loss has been a deep blow to a large number of friends, for he was essentially a "clubbable" man, and of the many clubs to which he belonged at none will his cheerful personality be more missed than at the "Fountain," of which he was an original member.

J. F. GEMMILL, M.A., M.D., D.Sc., F.R.S.,

Professor of Natural History, University College, Dundee.

WE regret to record the death by drowning of Dr. J. F. Gemmill, Professor of Natural History at University College, Dundee. His body was found on February 10th in the River Tay at Dundee esplanade, several hundred yards west of the Tay Bridge. He had been in indifferent health for some time.

James Fairlie Gemmill was a native of Mauchline, Ayrshire, and received his education at Mauchline Public School, Kilmarnock Academy, and Glasgow University. He graduated M.A. at Glasgow University with honours, and M.B., C.M. with high commendation in 1894. In 1900 he proceeded M.D. with honours, and in 1910 obtained the degree of D.Sc. For a time he worked as a research fellow in embryology at the University of Glasgow and as lecturer in zoology at the Glasgow Provincial Training College. In 1919 he was appointed to the chair of natural history in University College, Dundee. He had held numerous posts of distinction in the department of natural science, including that of president of the Natural History Society and Microscopical Society of Glasgow and honorary vice-president of the Scottish Marine Biological Association. He was the first president of this association while it was still known as the Marine Biological Association of the West of Scotland. He had also been for some years a Fellow of the Zoological Society.

Professor Gemmill's numerous publications dealing with problems in natural history included "The teratology of fishes" in 1912; "The lantern of Aristotle as an organ of locomotion in *Echinus*," published in the *Transactions of the Royal Society* in 1912; "Development of the starfish *Solaster endeca*," published in the *Transactions of the Zoological Society* in 1912; "Ciliation of asteroids and on the question of ciliary nutrition in certain species," *ibid.*, 1915; "Development and adult anatomy of the starfish (*Asterias rubens*)," published in the *Transactions of the Royal Society of London*, 1914; and "Development of the starfish (*Porania pulvillus*)," published in the *Quarterly Journal of the Microscopical Society*, 1915.

Professor Gemmill was unmarried. The interment took place at the Western Cemetery, Dundee, on February 13th.

JOHN CAMERON YOUNG, M.A., M.D.,

Medical Missionary, Keith-Falconer Medical Mission, Aden.

A CABLEGRAM from Abyssinia, whither he had gone on medical advice for rest and change, announces the death of the "Grand Old Man of Aden," Dr. Young. His many and varied activities for thirty-two years, in one of the most trying climates of the world, had made him known more widely than is the lot of most.

A soldier's son, John Cameron Young's strenuous life of work began at the early age of 10, when he was taken from school to earn his own living, and some years later he went through a full joiner's apprenticeship. While working at his trade he experienced a religious awakening that spurred him to devote his life to mission work. Undeterred by difficulties, he worked like Livingstone, to whom in later years he bore some personal resemblance, and successfully made his way, not only through the medical curriculum in Glasgow, but also through an arts and at least part of a theological course. Working at his trade in the vacations, and in term time earning some money by teaching and book-keeping, he managed to support himself during these years. After graduating M.B., C.M. in 1892, he was sent by the Free Church of Scotland to Sheikh Othman, ten miles inland from Aden, where mission work had been begun some six years previously by that brilliant athlete and Arabic scholar, the Hon. Ion Keith-Falconer.

Young started work with characteristic enthusiasm, and soon found himself embarrassed by the number of his patients. For many years he was handicapped by lack of suitable buildings. The hospital was the bungalow which Keith-Falconer had been building for himself at the time of his death, and was not designed for medical work. Moreover, it had not been built of teak, and the white ants soon rendered its upper floor unsafe, while lack of funds prevented its repair. In course of years, largely

through his own efforts, money was raised, the building was enlarged and repaired, and the new hospital was opened by the Resident of Aden in 1909. For the first time in the mission's history it was possible to do surgical work under reasonably good conditions. A rapid influx of patients resulted, the nominal hundred beds of the hospital were filled to overflowing, and so great was the demand for surgery that two whole days a week had to be devoted to this branch of the work. Only those who have experienced it know what a ten hours' day of operations means, with the shade temperature at 98°, as it is for months at a time in Aden.

That operative work by one living only a mile from the frontier of the Aden Hinterland, where every man goes armed, was not without its dangers to the operator, was proved by an incident in Dr. Young's career. He had been summoned to the neighbouring town of Lahej to operate for cataract on an Arab dignitary. His instructions as to dressings were disregarded by the patient, eager to use his eye, and sepsis ensued. Some days later Young's horse was found dead, stabbed in its stable in his compound. It was afterwards discovered that an emissary of his unfortunate patient had been sent to murder the doctor, but, being unable to make his entrance into the bungalow, had contented himself by killing the doctor's horse!

Working as he did in the midst of a more or less fanatical Moslem population, it was not to be wondered at that Young's preaching in the hospital won for him the title of "El Maghawī," "the deceiver." It pleased him when a patient, restored to health by his efforts, suggested altering a letter in the Arabic word and called him "El Makawī," "the strengthener." His interest in other parts of his work, the mission school, his work as chaplain to the Presbyterian and Wesleyan troops in the Aden garrison, and his English services for Europeans in the little Presbyterian church at Steamer Point, prevented him devoting sufficient attention to surgery to become a brilliant operator, but many things he did very well. Amputation at the site of election, often necessary as the result of the terribly prevalent tropical ulcer, Syme's amputation for such conditions as madura foot, and litholapaxy were among the operations he did best. He had no lack of surgical courage in an emergency, and a successful Caesarean section in a desperate case early in his career won him the devotion of an influential family.

One of the social reforms of which he was most proud was the stopping, in the neighbouring sultanate, of the barbarous custom, sanctioned by Moslem law, of chopping off the right hand as a punishment for theft. To arrest the haemorrhage the stump was plunged in boiling tar. Several of these unfortunates having come to him for treatment, in many cases involving reamputation, Dr. Young spoke to the Resident about it. The Resident, at that time General O'Moore Creagh, afterwards Commander-in-Chief in India, visited the Sultan and mentioned the subject. The Sultan was inclined to resent any interference in his domestic affairs, but Creagh tactfully suggested that Queen Victoria would be shocked to hear from him that his friend the Sultan of Lahej was in the habit of treating his subjects in this way, and finally asked the Sultan as a personal favour to give it up. On his way home General Creagh called at the mission bungalow to tell Dr. Young of the Sultan's promise to do so—a promise that was faithfully kept.

The outbreak of the local war in July, 1915, when Sheikh Othman was for eleven days in enemy hands, and after recapture was an armed camp till long after the armistice, put an end for the time to the mission's activities. Dr. Young was asked by the Government of India to act as port health officer in Aden, so releasing an I.M.S. officer for active service. He carried out these duties for the remaining period of the war, and afterwards for a time was acting civil surgeon and jail superintendent. As soon as the way was open he returned to the work he loved so well in Sheikh Othman, and laboured there till his death. It is characteristic of him that after his return to mission work he informed his committee that it need send him no more salary, as he had saved enough in his years in Government service to support him for the rest of his life.

For the last year, owing to the breakdown in health of his colleague, he was the only doctor in the mission. In a letter received by the writer just before the news came of his death he gives his statistics for the year. He had seen during the year 8,104 new out-patients, with 35,000 attendances; he had had 677 in-patients in the hospital; and he had performed 1,331 operations—no mean record for a man of 66.

The value of his work was recognized by the Government when in 1905 he was awarded the Kaisar-i-Hind silver medal "for public service in India," for his work in years of plague and famine. In 1912, for further service, the gold medal was conferred on him. In 1905 he had obtained the D.T.M. Liverpool.

Lieut.-Colonel H. F. Jacob, C.S.I., for many years First Assistant Resident in Aden and the greatest living authority on the Yemen, refers in glowing terms in his books to the value of the Keith-Falconer Hospital, and Dr. Young's work there, as a means of establishing friendly relations with a great part of the Arabian peninsula. So widespread is the hospital's reputation that it is no uncommon thing to have patients coming thirty and even forty days' journey, from the almost unexplored wilds of the Yemen, Asir, and the Hadhramaut, to seek the help of its medical staff.

Dr. Young's crowded life and his very large private correspondence did not leave him much time for literary work. What he wrote mostly took the form of articles for mission magazines and the *Expositor*. His little book entitled *Children of Arabia* has had a wide sale. For his M.D. thesis in 1921 he wrote on Arabian medical and surgical lore and practices.

A man of sterling moral rectitude, devoted to his duty as he saw it, untiring and absolutely unsparing of himself, extraordinarily generous, always the champion of the oppressed, thousands of his friends in many lands will feel that the world is the poorer by his passing. "He was ever a fighter," he has fought "one fight more, the last and the best."

A. MACR.

H. R. PRENTICE, M.B., M.R.C.P.,

Medical Superintendent, Seamen's Hospital.

WE regret to record the death, in his 47th year, of Dr. Hugh Ridley Prentice, which occurred at Greenwich on February 3rd. He was the eldest son of Thomas Ridley Prentice, a distinguished musician of his time and professor of the piano at the Guildhall School of Music, who in 1869 started some popular concerts at Brixton, and about 1880 gave concerts at Kensington Town Hall, called "twopenny concerts," for the working classes. His father died when Prentice was 15; from him he inherited a fondness for the study of music and a marked technical ability. It was one of his chief sorrows that his crippling disabilities should have made it impossible for him to exercise one of his most cherished hobbies. From his mother he inherited a taste for literary study, and his knowledge of philosophy added power and clarity to a mind always at once orderly and far-seeing. He had two brothers; one was killed in France in 1915, and the other, who resides abroad, survives him.

Prentice was educated at Weimar and at St. Bartholomew's Hospital, took his English Conjoint Diplomas in 1906, the M.R.C.P. in 1912, and graduated M.B., B.S. Lond. in 1913. For four years after qualifying he held the post of resident medical officer at the National Hospital for the Paralysed and Epileptic, Queen Square, where he worked directly under Sir Victor Horsley. He then commenced a consulting practice in Welbeck Street, selecting neurology as his particular study. In 1914 he was appointed assistant physician to the West End Hospital for Nervous Diseases, to the Belgrave Hospital for Children, and to the Seamen's Hospital, Greenwich. During the war he held a commission in the Royal Navy, and was seconded for duty at the Seamen's Hospital. After the war he was appointed medical superintendent of the Seamen's Hospital, retaining at the same time his position on the honorary medical staff of that institution, the while he still continued his connexion with the West

End Hospital for Nervous Diseases. It was soon after his appointment as superintendent that there appeared the first indications of the long and painful illness which eventually led to his death. His attitude throughout was one of philosophic courage, which masked his sufferings so effectively that only those who were most intimate with him were able to gauge their intensity.

He leaves a widow and three children, the eldest of whom is 5. By his death the Seamen's Hospital has suffered a great loss, for his tolerant clarity of mind and speech could always be relied on to guide his colleagues when intricate questions of policy were under discussion.

His many friends will learn with deep regret the news of the sudden death, on January 30th, of Dr. WILLIAM DAVID MOORE, who recently retired from the position of medical superintendent of Holloway Sanatorium, Virginia Water. While attending a committee meeting summoned to appoint his successor, Dr. Moore was suddenly seized with a heart attack, and died soon after. He was born in 1858, and received his medical education at Queen's College, Belfast, Galway, and the London Hospital. He graduated M.D., M.Ch. of the Royal University of Ireland in 1880, and obtained the diploma L.M. of the Royal College of Physicians of Ireland in 1888. After acting for some time as an assistant in private practice, he became assistant medical officer to the Wilts County Asylum, and subsequently, after another period of private practice, was appointed medical officer of health at Alresford. In 1892 he became senior assistant medical officer at the Holloway Sanatorium, and in 1899 was appointed medical superintendent in succession to Dr. Sutherland Rees-Philipp, whose recent death abroad we reported in our issue of January 23rd. Dr. Moore devoted himself wholeheartedly to improving this institution, and bringing it into the front rank of hospitals dealing with mental diseases. In his earlier days he took an active interest in athletics, including, rowing, swimming, and skating. He represented Ireland in international Rugby football in 1878 and the two following years. He was a member of the Wiltshire county cricket team, and reached the semi-final of the amateur golf championship. His great sympathy, tact, and patience won him an abiding friendship with his patients and the hospital staff, and his memory will long be kept green in the hearts of those who were associated with him. His wife predeceased him in 1917.

On February 5th, after an operation for duodenal ulcer, there passed away in London Dr. HENRY JAMES GORRIE, who, since the war, had built up an extensive dental practice in Sutton, and who also held the appointment of dental surgeon to the Banstead Mental Hospital. Dr. Gorrie was educated at Dundee University College and Edinburgh, where he obtained the diplomas L.D.S.R.C.S. in 1905, and L.R.C.P., L.R.C.S., and L.R.F.P.S. in 1906. Dr. Gorrie at first practised dentistry with his father in Dundee, and later at Carnoustie, Forfarshire. Immediately on the outbreak of war he was mobilized with the 3rd Highland Field Ambulance, and served in France with the 51st Division throughout the whole campaign, except for a short period of illness. For his war service he was decorated with the O.B.E., and he retired on demobilization with the rank of major, R.A.M.C.T. He returned home in poor health, but started a practice in Sutton which steadily increased. A colleague writes: To have known Henry Gorrie, as I have, for thirty-five years was a privilege. He was a man of the most charming personality and of the greatest sincerity, whose cheerful disposition endeared him to everyone. He was always breezy and full of that dry pawky humour characteristic of his Scottish nationality. Of strong convictions, he only laughed at difficulties, and in all the years I knew him I never heard him complain or say aught against any man. Gorrie had many friends, both in and out of the profession: few could command such a wide circle of constant friends, who will not readily find another so true and sincere as he was. To those in the profession less fortunate than himself his charity and kindness was

A meeting of the Fellows will be held at the College on Thursday, July 1st, at 2.30 p.m., for the election of four Fellows into the Council in the vacancies occasioned by the retirement in rotation of Mr. W. G. Spencer and Mr. E. W. Hey Groves and by the resignation of Sir Charles Ballance and Mr. James Sherren. Notice of the meeting will be given to the Fellows by advertisement and by circular on March 5th. The last day for the nomination of candidates will be March 15th. A voting paper will be sent on March 30th to every Fellow of the College (except women Fellows) whose address is registered at the College.

Hunterian Lectures.

Sir Arthur Keith's remaining three Hunterian lectures on "Fossil remains of ape and man and their bearing on the evolution of human races" will be given on February 22nd, 24th, and 26th.

Queen Victoria Jubilee Institute for Nurses.

Sir D'Arcy Power was reappointed to represent the College on the council of Queen Victoria's Jubilee Institute for Nurses for three years from March 1st next.

Diplomas of Fellowship were granted to Mr. Alan Cameron Maconie and Mr. Harold Burt-White, who have now complied with the regulations.

Diplomas of Membership were granted to 179 candidates, including 35 women, and diplomas in ophthalmic medicine and surgery were granted jointly with the Royal College of Physicians of London to 19 candidates. (The names of the diplomates were published in the report of the comitia of the Royal College of Physicians printed in our issue of February 6th, p. 266.)

Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

THE House of Commons has again considered Supplementary Estimates this week, and has debated the new Treaty with Iraq. Orders laid on the table of both Houses include a number dealing with National Health Insurance and two concerning the General Nursing Council for England and Wales—one amending the rule relating to reciprocal registration and the other including a syllabus of subjects for examination for the certificate of general nursing. The Public Health and Housing Group of the Conservative party in the House of Commons met on February 16th and considered its operations for the session.

The Harnett Case.

In the House of Commons on February 15th, in Committee of Supply on a Supplementary Estimate for £26,660 for the salaries and expenses of the Board of Control (Lunacy and Mental Deficiency), England, and for grants in respect of maintenance for certain ex-service mental patients, and of certain damages and costs in a legal action.

Mr. Pethick-Lawrence called attention to the sum of £2,800 which appeared in the estimate in respect of the case of Harnett v. Bond. In this case, he said, the plaintiff, Mr. W. S. Harnett, brought an action against Dr. Bond, a Commissioner of the Board of Control, and another, on the ground of alleged wrongful imprisonment as a lunatic. He was released, according to the statement of the medical officer of the asylum, on twenty-eight days' leave. He found that his brother was in charge of his property, and went to the Board of Control to have the matter investigated. While he was there he interviewed a member of the Board, Dr. Bond, who detained him, and sent him back to the asylum, where he remained in custody for eight years. The jury awarded £25,000 damages against Dr. Bond and £5,000 against the medical officer of the asylum. On appeal, the Court of Appeal ordered a new trial as between the plaintiff and Dr. Bond. The plaintiff appealed against this judgement to the House of Lords, who dismissed the appeal. At this stage the Board of Control offered a sum of £250 as damages and £2,500 in respect of plaintiff's costs. After negotiations this offer was accepted. The case was a serious one, as this unfortunate man had not merely suffered eight years' detention as a lunatic, when he was sane, but he had also spent a sum of over £25,000 to obtain his rights. The taxpayer (who had had to pay the sum of £3,000 or £4,000 already) was now called upon to pay a further sum of £2,800.

Sir Kingsley Wood (Parliamentary Secretary to the Ministry of Health), in reply, said he thought that Mr. Pethick-Lawrence had been wholly misinstructed as to the facts of the case. He (Sir Kingsley Wood) intended to be very guarded in his reply, as he understood that Mr. Harnett had brought another action in the King's Bench Division against the doctor who gave the first certificate of his insanity.

Mr. Short asked the chairman (Mr. Hope) if it was right for the Committee to discuss the matter, seeing that it was again to be brought into court. He suggested that the vote should be withdrawn pending the final decision of the case.

Sir Douglas Hogg (Attorney-General) said it was possible to discuss the vote, which was necessary to carry out the arrangement come to in the first action, without touching on the issue in the forthcoming case.

The Chairman said that in the circumstances it would be better to withdraw the vote until later to allow him to consider the situation. He would not like to rule on the matter right off in case it might be taken as a precedent.

The vote was postponed accordingly.

Small-pox.

Answering Mr. Lansbury, Mr. Chamberlain said that from January 1st, 1925, to February 6th, 1926, 1,966 cases of small-pox had been notified in the county of Durham. In two instances small-pox had been entered on a death certificate as one of the causes of death. Medical officers of the Ministry of Health had paid numerous visits to advise and assist the local authorities and their officers. Reports of these medical officers indicated that the outbreak might be attributed to the spread of the disease from other infected areas, and that the present prevalence was in large measure due to the neglect of vaccination and in some districts to lack of adequate hospital accommodation. He did not think that the districts which were worst affected were those where men had been most impoverished, and he could not say what percentage of cases had been vaccinated. It would be difficult to draw any safe deduction from the figures in his possession, but they did not bear out the suggestion that the cessation of poor relief in a union was the cause of special prevalence of disease in that union, seeing that prevalence was less than in an adjoining union.

Mr. Chamberlain gave statistics showing that in the week ended January 24th, 1925, one case of small-pox was notified in county Durham, 11 cases in the week ended June 27th, 12 cases in the week ended September 26th, and 104 cases in the week ended December 26th. In 1925 the figures were: weeks ended January 2nd, 98 cases; January 9th, 138; January 16th, 139; January 23rd, 177; January 30th, 182; and February 6th, 213 cases. The areas where the disease was most prevalent were: Gateshead C.B., Blaydon U.D., Chester-le-Street U.D., Whickham U.D., South Shields C.B., Auckland R.D., Chester-le-Street R.D., Easington R.D., Houghton-le-Spring R.D., Lanchester R.D., Sunderland R.D., and Spennymoor U.D.

Mr. Davidson, Financial Secretary of the Admiralty, told Mr. Bromfield that restrictions on leave for naval officers and men in districts where small-pox was prevalent were necessary in view of the fact that, although every reasonable precaution was taken to ensure the protection of every individual in the navy against this disease by vaccination, there still must be a certain proportion unprotected, either by oversight or on the grounds of conscientious objection, to which must be added recent entrants who had not yet undergone protection by vaccination. In addition, dockyard employees were not under the same control as naval personnel as regards vaccination, and consequently a large proportion of them were non-immune, and as naval personnel and these employees were intimately associated infection might be carried either by a person in the early stages of small-pox or by the clothing of one who had been recently in contact with a case. No precaution should be neglected to prevent a case of small-pox occurring in one of His Majesty's ships or establishments, as, apart from the menace to health, great expense was incurred in isolation and destruction of clothing, bedding, etc. In addition, there was the inconvenience and expense of keeping all contacts of a case in isolation and under observation for fourteen days.

Sir Kingsley Wood, replying, on February 15th, to Sir William Davison, stated that the number of cases of small-pox in England and Wales had increased from 311 in 1919 to approximately 5,300 in 1925. The Minister of Health had no information as to the number of persons not protected by vaccination, but there could be little doubt that it had been steadily increasing since the war, although it was generally found that considerable numbers of persons presented themselves for vaccination when any serious outbreak of small-pox took place. The Minister had no information as to the number of infant children living to-day who were unvaccinated. In 1923, the last year for which complete information relating to the vaccinations of infants was at present available, 758,404 births were registered in England and Wales. Of these, 395,553 had not been vaccinated by January 31st, 1925. The percentage of vaccinations to births in 1923 was 47.8, and the corresponding percentage for 1905 was 75.8.

Sir William Davison asked whether the Ministry of Health would issue a leaflet urging upon the public the desirability of protecting themselves against small-pox by vaccination. Sir Kingsley Wood said he would put this suggestion before the Minister. Sir Henry Craik asked whether the Minister did not consider that the time had come to take legislative steps to protect the people. No answer was returned.

Encephalitis Lethargica.

Sir Kingsley Wood informed Mr. Ammon that the departments concerned were considering the best means of providing for such cases as that of the young man charged with theft at Lambeth on January 5th, who was found to be suffering from the after-effects of encephalitis lethargica. The arrangements made by the Metropolitan Asylums Board for institutional treatment of children suffering from mental after-effects of this disease provided for the ordinary hospital accommodation of the patients and for all necessary treatment and medical care. The Home Secretary told Mr. Ammon that at places of detention to which young persons under 16 were remanded medical attendance was usually afforded by a doctor in general practice, but where mental trouble was suspected the case might be referred to a school medical officer or other specially qualified doctor. Officers over 16 were remanded to prisons where the medical officers were experienced general physicians and surgeons of good qualifications, with special

experience of insanity and mental deficiency. The medical examination of young offenders was being considered by the committee appointed last year to inquire into the treatment of young offenders.

Bills.

Dr. Fremantle has introduced a Midwives and Maternity Homes Bill, to amend the Midwives Acts, 1902 and 1918, and to provide for the registration of maternity homes and for purposes connected therewith. The bill is backed by Major Hills, and has been prepared in consultation with the Ministry of Health. It consists of two parts. The first is for amending the Midwives Acts to provide for the better control of unqualified midwives, for decreasing the deficit in the funds of the Central Midwives Board, which is due to the inclusion in the roll of midwives published annually of the names of large numbers of women who, for one reason or another, are not practising; for the payment of compensation to midwives who are suspended from practice through no fault of their own; for fixing a time limit for the rendering of claims for fees by medical practitioners called in by midwives in emergencies; and for certain other purposes. Part II is for the registration and inspection of maternity homes by the councils of counties and of county boroughs.

Objection having been taken to the second reading of the Bethlem Hospital Bill, consideration of it has been deferred for a month.

The Home Secretary hopes to reintroduce the Lead Paints Protection Bill very shortly.

Silicosis.—On February 15th Mr. Rennie Smith asked the Home Secretary if he could see his way to introduce amending legislation with regard to compensation for silicosis under the Refractories Industries (Silicosis) Scheme, and, in particular, those clauses which dealt with workers who had been employed for twenty years in industries where this disease was liable to be contracted and who, after twenty years' employment or more, had left the industry. Sir W. Joynson-Hicks replied that a workman who had left the industries could apply for compensation at any time if totally disabled by silicosis. In the case of partial incapacity, the claim must be made within one month after he had left the employment. In view of the great difficulties in dealing with claims put forward long after the employment had ceased, these provisions seemed to him very favourable to the workman, and the departmental committee which recently inquired into the work of the scheme made no recommendation for any alteration. He was not prepared, therefore, as at present advised, to propose any amendment. Sir W. Joynson-Hicks also stated that he was informed that out of the 547 persons examined in the Wadley Bridge area of Yorkshire, only 15 were certified to be suffering from silicosis. Special regulations for the prevention of the disease had been put in force in the local works, and he was advised that the conditions had greatly improved. This point would continue to receive the special attention of the department.

Miner's Nystagmus.—On February 16th Colonel Lane-Fox, Secretary for Mines, in reply to Mr. W. Paling, said that the number of certificates of disablement of coal-miners through nystagmus given by certifying surgeons was: in 1921, 1,986; in 1922, 4,047; in 1923, 4,050; in 1924, 3,446. The figures for 1925 had not yet been compiled by the Home Office. Sir H. Barnston, on behalf of the Home Secretary, in reply to Mr. Paling, also stated that the number of new cases of miner's nystagmus for which compensation was paid under the Workmen's Compensation Acts in each of the years 1921 to 1924 was as follows: 1,913 in 1921, 4,092 in 1922, 3,883 in 1923, and 3,271 in 1924. The figures for 1925 were not yet available.

National Insurance.—The Minister of Health has at present no information showing what it would cost to provide allowances for dependants of sick insured persons on the same scale as those now allowed for the dependants of insured persons under the Unemployment Insurance Acts. He understands that it will be dealt with in the forthcoming report of the Royal Commission on National Health Insurance. Mr. Chamberlain informed Mr. Rhys Davies, on February 15th, that he had received a copy of Memorandum 273 I.C., Post-Confinement Certification, dated December, 1925, issued by the Scottish Board of Health to all insurance practitioners in Scotland. There was no evidence that insurance practitioners in England and Wales were under the misapprehensions which the memorandum was designed to correct, and it was not proposed to issue a similar memorandum in England and Wales.

Pensions.—Major Tryon (Minister of Pensions) has stated that the present arrangements for supply of artificial metal legs were working satisfactorily, and he was not prepared to reconsider them. The few cases in which requests were made for a special make of limb not covered by the present contracts were considered by a board of surgeons constituted for the purpose. Supplies were arranged where necessary in accordance with their advice. Answering Mr. T. Kennedy, Major Tryon said he had issued instructions that in the rare case of an applicant discharged from the service for more than seven years, where an old wound, thought to have been healed, had broken down, and the man was in need of urgent surgical treatment, immediate steps should be taken to provide such treatment. Such cases were, for the most part, restored by treatment, but if in any instance the man was found after treatment to be seriously incapacitated, consideration

would be given to the making of an appropriate grant. This was not a new policy. In reply to Mr. Windsor, Major Tryon said that 4,863 claims in respect of tuberculosis were made during 1925, of which 1,314 were admitted.

Physique of Recruits.—Out of each 1,000 recruits rejected for the British army on examination in 1924-25, 30.11 were rejected for defects of the lower extremities, 14.10 for deficient chest measurement, 20.02 for insufficient weight, 32.39 for defective vision, 40.45 for diseases of the ear, 47.69 for diseases of the heart, 11.73 for diseases of the veins (varix), 32.78 for loss or decay of many teeth, 10.95 for varicocele, and 19.63 for flat-feet. Of recruits accepted for the navy in 1925, 2.67 per cent. were invalidated out within twelve months of acceptance.

Prison Medical Officers.—Answering Dr. Watts, the Home Secretary said he was unaware that certain prison medical officers were not getting the full benefit of the recommendations of the Stanhope Committee as regards increases of salary. Therefore the question of his inquiry into this matter did not arise.

Naval Medical Service.—The total number of medical and dental officers, sick-leath staff, nursing and massage sisters, and pharmaceutical staff under the Admiralty is 665 at home and 110 abroad. The annual cost of this staff at home is £135,422 and abroad £29,300. The maximum home accommodation for patients is 3,040 and average daily number 1,323. Abroad the maximum accommodation is 654 and average daily number 311.

Maternity and Child Welfare in Scotland.—On February 16th Sir J. Gilmour, the Secretary for Scotland, replying to Mr. N. McLean, said that under the maternity service and child welfare schemes in Scotland no payments of grant were made directly to maternity institutions, but where a local authority had made approved arrangements with a voluntary institution or itself provided an institution the approved cost ranked against the maternity and child welfare grant. The whole question of the finance of voluntary hospitals in Scotland had been the subject of a remit to a special committee, whose report he had just received. (See SUPPLEMENT to BRITISH MEDICAL JOURNAL of February 13th, p. 54.)

National Birth Rates.—Answering Sir N. Grattan Doyle, Mr. Neville Chamberlain gave the following birth rates of European countries in the latest years available:

Birth Rate per 100 Population.		
England and Wales (1925)	1.83	Netherlands (1924) ... 2.52*
England and Wales (1924)	1.88	Belgium (1924) ... 1.99
Sweden (1924) ...	1.81*	Spain (1924) ... 2.99*
France (1924) ...	1.89	Hungary (1924) ... 2.68

* Provisional.

Contraceptive Literature.—The Home Secretary, in reply to Sir N. Grattan Doyle, said he had received numerous complaints from members of the medical profession and others regarding the transmission through the post of circulars advertising contraceptives. In conjunction with the Home Office, the Director of Public Prosecutions had given the subject close attention, and would continue to take action in cases which appeared to involve a contravention of the law. The success of such proceedings depended upon the magistrates being satisfied that the postal matter was in fact indecent, and the divided state of public opinion had been reflected in the decisions given. The Home Secretary did not know of any further steps which he could usefully take.

Notes in Brief.

Measures for the protection of the civil population against poison gas are still under consideration, but the Government deems it inexpedient to give specific information.

Negotiations have been concluded between the Air Minister and the life insurance companies whereby the companies have reduced their annual premiums to cover flying risks in the case of R.A.F. officers.

The Government is unable to promote legislation to amend the provisions of the Dangerous Drugs Amendment Act, 1923, as applied to animal medicines.

A discussion on the Public Health (Preservatives in Food) Regulations is to be arranged on the vote for the Minister of Health's salary.

The Under Secretary for India states that outside doctors are or rarely neither allowed nor needed for the attendance of sick persons in gaol.

The Minister of Health cannot at present consider the granting of free licences and the making of free tuberculin tests for producers of Grade A milk.

The Home Secretary does not propose to appoint a committee to consider tests for drunkenness.

Sir Kingsley Wood states that there is nothing in Section 5 of the Dentists Act, 1921, as interpreted hitherto, to prevent any co-operative society or similar body from arranging for the dental treatment of its members, provided it does not seek any profit in so doing.

During the financial year 1924 £21,180 was expended in administration, as apart from capital expenditure, on medical and sanitary services by the Government of the Gambia.

Medical News.

SIR GEORGE NEWMAN, K.C.B., will deliver the Hunterian Oration at a meeting of the Hunterian Society of London to be held at the Mansion House, on Monday, February 22nd, at 9 p.m. His subject is the relation of the general practitioner to preventive medicine.

DR. E. GRAHAM LITTLE, M.P., has been elected a corresponding member of the Danish Dermatological Society and of the Royal Society of Medicine of Budapest, and honorary member of the Italian Society of Dermatology and Syphilography.

THE sixth biennial Sydney Ringer lecture will be delivered at University College Hospital Medical School by Dr. G. V. Anrep on Thursday, March 4th, at 5 p.m.; the subject is the regulation of the coronary circulation. The lecture is open to all qualified practitioners and medical students.

The annual dinner of the Glasgow University Club, London, postponed from December 4th last, will take place at the Trocadero Restaurant, Piccadilly, on Friday, February 26th, at 7.15 p.m. for 7.30 precisely. The chair is to be taken by Sir Henry Craik, Bt., K.C.B., M.P., and Sir Martin Conway, M.P., will respond to the toast of "The Guests." Any Glasgow University men who, though not members of the club, would like to attend will kindly communicate with the Honorary Secretaries, 62, Harley House, N.W.1.

A CHADWICK public lecture on the activated sludge process of sewage treatment will be given by Mr. H. T. Calvert, D.Sc., in the lecture hall of the Institution of Civil Engineers, Great George Street, Westminster, on Friday, February 26th, at 8 p.m. Admission is free.

A PROVINCIAL meeting of the Maternity and Child Welfare Group of the Society of Medical Officers of Health is being held in Birmingham on February 19th and 20th. Papers are being read on child welfare work in the United States and Canada, and on the effect of defective ante-natal care and obstetrics on the health of the mother. Clinical demonstrations have been arranged in various Birmingham clinics.

At a meeting of the Sociological Society to be held at the rooms of the Royal Society, Burlington House, Piccadilly, W., on Tuesday, February 25rd, at 8.15 p.m., Dr. Binnie Dunlop will speak on the Malthusian principle and sociology. The chair will be taken by Sir Francis Younghusband.

THE Grade "A" (Tuberculin Tested) Milk Producers Association is arranging a conference at University College, Reading, for March 23rd and 24th, on similar lines to that held in 1924. On the first day, under the chairmanship of Dr. R. King Brown, medical officer of health for Bermondsey, the subjects to be dealt with include the present position of certified and Grade "A" (tuberculin tested) milk in Scotland, the steps taken by the (Ministry of Agriculture to promote the production of graded milk, and the cost of producing Grade "A" (tuberculin tested) milk. The chairman for the second day will be Dr. A. A. Mussen, medical officer of health for Liverpool, and discussions will be held on the value of the tuberculin test to the dairy farm, the growth of grade milk production, and the control of tuberculin tested milk from its source to the consumer. Visits will be paid to graded milk producers' farms, to district distributors, and the College Farm and National Institute for Research in Dairying. On the first evening a dinner will be held under the chairmanship of Mr. W. M. Childs, the Principal of University College. Residential accommodation will be available at St. Patrick's Hall. Tickets and further information may be obtained from the honorary secretary, Lieut.-Colonel C. Maddock, C.I.E., M.D., Foxglade House, Shinfeld, Reading.

THE Fellowship of Medicine announces that on February 25th, at 5 p.m., a lecture will be given by Mr. Frank Kidd entitled "Some points in the treatment of tuberculosis of the urogenital tract," at 11, Chandos Street, free to all members of the medical profession. On the same date Mr. L. B. Barrington-Ward will give a special demonstration in clinical surgery at the Royal Northern Hospital at 2 p.m. to members of the Fellowship or holders of its general course tickets. The following courses will be continued through the week: General medicine and surgery at the Queen Mary's Hospital, Stratford; clinical instruction in venereal disease at the London Lock Hospital; and a combined course in diseases of children at the Paddington Green Hospital, Victoria Hospital (Chelsea), and the Children's Clinic. During the first fortnight of March there will be a daily afternoon post-graduate course at the Royal Eye Hospital. In the early part of March the Westminster Hospital will give a special course in bacteriology, during the last three weeks in March the Chelsea Hospital for Women will hold a course in gynaecology, and during the last fortnight the Brompton Hospital will arrange an all-day course in diseases of the chest. The Hampstead

General Hospital will hold a late afternoon course in general medicine and surgery from March 15th to 27th, while the Tropical School will begin a course of two sessions weekly on March 16th. Copies of all syllabuses and of the general course programme may be had from the Secretary of the Fellowship of Medicine, 1, Wimpole Street, W.1.

PROFESSOR S. LYLE CUMMINS will hold an intensive post-graduate course on tuberculosis from April 12th to 17th, for medical men and women specially engaged in tuberculosis work. The course will consist of clinical meetings with demonstrations at Glan Ely Hospital, Fairwater, near Cardiff, and at Cefn Mably Hospital, near Cardiff, x-ray demonstration and reading of films at Glan Ely Hospital, and daily lectures and pathological demonstrations at the Welsh National School of Medicine, Cardiff. The fee for the course, which will be limited to ten members, is three guineas. Names should be sent immediately to the Honorary Secretary, Joint Tuberculosis Council Post-Graduate Courses, at 19, Brunswick Square, Cumberwell, S.E.5, from whom particulars can be obtained.

THE Scottish Board of Health has appointed Dr. Thomas Dymock Kennedy to the post of district medical officer (medical referee) in that department. Dr. Kennedy is at present Senior Medical Assessor for Scotland under the Ministry of Pensions, with which department he has served for the past six and a half years.

DR. MIRALLÉ has been nominated professor of clinical medicine, and Dr. Brelet professor of medical pathology, in the Nantes medical school. Dr. Léri has succeeded Professor Guillaïn as President of the Société de Neurologie, and M. Emile Perrot, professor of materia medica in the Paris Faculty of Pharmacy, has succeeded Dr. Gallois as president of the Société de Thérapeutique.

THE Ella Sachs Plotz Foundation, which provides grants in aid of scientific research in different parts of the world, gave thirteen grants in 1925, as compared with eight in the previous year. The United States received nine grants and Strasbourg, Vienna, Estonia, Berlin, and Hungary one each. Applications for grants during the coming year should be sent before May 15th to the secretary of the executive committee, Dr. E. W. Peabody, Boston City Hospital, Boston, Massachusetts. It is announced that researches will be favoured which are directed towards the solution of problems in medicine and surgery. In both 1925 and 1924 four of the investigations aided were related to chronic nephritis.

In a communication on engineering services in hospitals and asylums read before the Institution of Heating and Ventilating Engineers, Mr. H. G. Cathcart gave figures showing the actual amount of fuel and water consumed per annum in different types of institutions. Much economy in fuel was effected by a modern centralized plant as compared with the old-fashioned type of scattered heating and hot-water units. Mr. Cathcart advocated the use of low-pressure hot water, and as simple a plant as possible consistent with efficiency. All pipes and radiators should be accessible for cleaning purposes and the heating surface evenly distributed. He also gave figures as to the consumption of gas and electricity per head per annum in different institutions.

In commemoration of the thirtieth anniversary of his appointment to the Bucarest Faculty of Medicine, Dr. T. Jonnesco will receive on February 21st a presentation volume containing an account of his life, together with a congratulatory address.

DR. DOLÉRIS, ex-president of the Académie de Médecine of Paris, has been nominated Commander of the Legion of Honour. The nomination of Professors T. Madsen and P. Teissier of Paris as honorary foreign members of the Royal Academy of Medicine of Belgium has been approved by royal decree.

DURING the first six months of 1925 small-pox in America and Canadian cities was more than three times as fatal as in 1923, the mortality last year being 3.5 per cent., as compared with 1 per cent. in 1923.

M. RAKOVSKI, the new ambassador of the Soviet Republics in Paris, received a medical training in Paris, Nancy, and Montpellier.

It is announced that under the auspices of the Health Organization of the League of Nations special laboratory courses on malaria will be arranged for medical practitioners in London, Paris, and Hamburg during next summer. Dr. Andrew Balfour will hold a theoretical and laboratory course in London from June 21st to July 24th, and Professor Brumpt and Professor Nocht will arrange similar courses in Paris and Hamburg respectively. Field work, lasting several months, in such infected countries as Spain, Italy, Corsica, Jugo-Slavia, and, possibly, Palestine, will follow the theoretical part. Further information may be obtained from the Health Section of the Secretariat of the League of Nations at Geneva.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the **BRITISH MEDICAL JOURNAL** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the **BRITISH MEDICAL JOURNAL** must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the JOURNAL, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBERS of the British Medical Association and the **BRITISH MEDICAL JOURNAL** are **MUSEUM 9801, 9802, 9803, and 9804** (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR of the **BRITISH MEDICAL JOURNAL**, *Aitiology Westcent, London.*

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate Westcent, London.*

MEDICAL SECRETARY, *Mediscera Westcent, London.*

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 4361 Central).

QUERIES AND ANSWERS.

PAGET'S DISEASE.

"M.R.C.S." has the misfortune to suffer from Paget's disease, chiefly affecting the right leg; this has been troublesome for about six months and gets worse. His head is enlarged, but this became quiescent two to three years ago. He asks if there is any treatment likely to do him good. The leg gets very painful after exertion and again at night. He has tried iodides, salicylates, and endocrines, together with various forms of electricity, but without appreciable relief.

* * We are afraid that treatment of this affection can only be palliative. A late distinguished member of our profession found his symptoms alleviated by a protein or meat diet. The pains in the long bones appear to be due to tension, and relief has been experienced after osteotomy, performed to correct deformity and not with the intention of relieving pain. If the pains are severe there could, we think, be little risk in drilling into the bone in various situations, which could be done subcutaneously. Our correspondent appears to have tried the usual internal remedies except mercurials, which he does not mention. They might be given a trial.

PETROLEUM IN THROAT SPRAYS.

"J. M. G." asks whether there is any objection to the constant use of liquid petroleum as a basis for a nose and throat spray, particularly with regard to the possible danger of setting up cancer. He would like to know of a good formula for a spray with either a petroleum or an oil basis, for frequent use as a safeguard against influenza and common colds.

* * The experimental production of cancer by paraffin is believed to be due to impurities in the paraffin; there is no evidence that the Pharmacopoeial paraffinum liquidum produces cancer, and it is commonly used in the manner indicated. The following is a good oil spray: Chloretone, gr. xv; camphor, gr. xl; menthol, gr. xl; olei cinnamoni, m viij; liq. paraffin. ad 3ij.

LEAD SALTS IN CANCER.

Dr. G. C. BELCHER (Birmingham) writes: I would remind Colonel Rowcroft (*JOURNAL*, February 6th, p. 263) that the dose of lead acetate he advocates is the average one. Each case is judged upon its merits; different individuals vary with this drug. Lead in particular affects the individual differently; boys as apprentices to the plumbing trade have a probation for a few weeks to see if they can without danger keep to the trade. So it is in all cases of lead workers. In some of my patients 1/2 grain daily could not be tolerated; in others as much as 5 grains, and in one case 7 grains, was required to produce the well known toxic effects of lead; but the dose I advise is one already stated by me—1½ grains t.d.s., as an average dose.

INCOME TAX.

Allowance for Insurance Premium.

"R. A. D." is converting his life assurance into an endowment policy payable at the age of 65; does this affect his income tax allowance?

* * It is assumed that our correspondent is, in law, discontinuing one policy and entering into a new contract. On that basis he will be entitled to the relief in respect of the premiums paid, at half standard rate if his total income does not exceed

£1,000, three-quarters if not exceeding £2,000, and the full rate if it exceeds that figure—subject to the restriction that the amount of the premium allowed exceeds neither 7 per cent. of the capital sum payable at death or 65, nor one-sixth of his total income, and to the further restriction that the rate at which the allowance is made does not exceed 3s. It is on this last point that "R. A. D." may possibly lose, as that restriction applies only to policies taken out after June 22nd, 1916, and his first policy may have been prior to that date, in which case he may lose if his total income amounts to £2,000.

LETTERS, NOTES, ETC.

OPEN-AIR SHELTERS.

THE "Papworth Industries," Cambridge, which is part of the well known tuberculosis colony, to the work of which we have often referred, is prepared to supply shelters of various types for the home treatment of tuberculosis and other diseases in which sleeping in the air is required. To overcome the difficulty of introducing these shelters into gardens through narrow doors one type—the "County" shelter—can be supplied with a jointed roof and front. Another pattern is arranged to revolve, so as to avoid rain and wind blowing into it; and a third, more elaborate, type is constructed so that air can enter simultaneously through all four sides, any of which can be closed quickly if desired.

GOITRE IN NEW ZEALAND.

Dr. E. H. WILKINS (Birmingham) writes: In the discussion on goitre reported in your issue of February 6th (p. 241) Dr. Cole is reported as saying that in New Zealand goitre is confined to narrow sunless valleys. Having lived in New Zealand ten years I am in a position to say that this is not so. One of the chief goitrous areas, for instance, is on the Canterbury plains. Goitre in New Zealand appears to have a definite relation to water of soil, but not to bacterial infection of the water (see two papers by Hercus and Baker in the *New Zealand Medical Journal* and reports of the Health Department during the last few years).

MEDICAL MISSIONS.

"EXPERIENCED" writes: The article on the needs of medical missions, in the *JOURNAL* of February 6th (p. 255), gave no indication as to the cause of the needs. One is, of course, money. I think only one mission committee has made any arrangement by which a doctor can serve for a period and have a certain sum to start him in practice after. This must affect many men and some women doctors who cannot undertake life service. Another cause is the precise opinion on theological points required by some societies. I believe the Anglicans are the worst offenders. Obviously it is difficult for a committee chiefly composed of good ladies and clergy to realize that points of importance to padres and perhaps teachers are meaningless for doctors and nurses. One could imagine a doctors' missionary society which would supply doctors where needed: theological agreement with the mission concerned being considered desirable but not essential. It would fail under the present system, because committees would rather have hospitals closed and sick people left uncared for than employ practitioners with unorthodox religious views. A possible solution would be that members of missionary committees should be bound to employ for themselves no doctor whom they could not recommend for their mission.

THE HEALTH OF THE JEWISH CHILD.

At a recent meeting organized by the Jewish Health Organization in Whitechapel an address was given by Dr. A. Elchholz, chief inspector of the Board of Education, on the health of the Jewish child. He said that in the Middle Ages, when the greater part of Europe was intellectually dark, Jewish practitioners of medicine in Northern Africa, Western Asia, and Southern Europe kept the traditions of science alive. He had recently found in a rare Italian medical work, published in 1487, copious marginal notes in Hebrew, the work of some ancient Jewish doctor, who had recorded his own observations and compared them with those in the text. The Jewish Health Organization was now actively concerned in investigating the hygienic and medical conditions of Jewish school children, with special reference to defects of vision; these were frequently associated with measles and scarlet fever, which caused weakening of the muscles. Insufficient attention was paid by Jews to the need of recuperation after measles in childhood. It was possible that care in this respect and avoidance of undue fatigue and overwork, especially at night, would protect the children from visual strain. In addition to their school work, Jewish children had to devote time in the evenings to the study of Hebrew and of their religion. On February 27th, under the auspices of the Jewish Health Organization, a lecture on social hygiene and the home will be delivered to women by Professor Winifred Cullis, and on March 6th by Dr. Israel Feldman to men on the perils of ignorance.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 39, 40, 41, 44, and 45 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 42 and 44.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 63.

A British Medical Association Lecture ON THE SURGICAL ASPECTS OF CERTAIN DISTURBANCES OF THE INVOLUNTARY NERVOUS SYSTEM MET WITH IN THE ALIMENTARY TRACT.*

BY

JOHN FRASER, M.D., CH.M.,

REGIUS PROFESSOR OF CLINICAL SURGERY IN THE UNIVERSITY
OF EDINBURGH.

MR. PRESIDENT AND GENTLEMEN,—I thank you for the privilege you have afforded me in asking me to speak to you this afternoon. I am grateful to you for many reasons. I confess I enjoy a visit to London, and as I walked along Piccadilly this morning it seemed to me that George Colman's lines still hold good:

"Oh, London is a fine town,
A very famous city,
Where all the streets are paved with gold,
And all the maidens pretty."

The reputation of 1797 applies to-day, and we country mice from the provinces are enamoured of it all. As I sat just now on the edge of the fountain in the courtyard, before Professor Gask took charge of me, I felt conscious of the privilege of speaking on this historic spot, for, if the walls are modern, the spirit is as old as that of Rahere, the founder and prior of 1123.

It is my intention to speak on a subject which interests me greatly, and I would I could garb it attractively, so that you too might be interested. It is necessary that I introduce the subject with a brief reference to the physiological anatomy of the important body element—the involuntary nervous system.

FIG. 1.—Diagram showing relation between pre-ganglionic and post-ganglionic fibres. (From *Essentials of Physiology*, Bainbridge and Menzies.)

Langley in 1898 grouped together the efferent nerve fibres and ganglionic systems which control the unstriated and cardiac muscles and the glandular tissues under the name of "the autonomic nervous system," and this work, together with that of Gaskell, Bayliss, Starling, Langdon Brown, and many others, has put our knowledge of this most interesting though intricate system upon a clear basis.

A GENERAL APPRECIATION OF THE ANATOMY.

It seems to me that we get an interesting appreciation of the peculiar distinctions of the involuntary nervous system if we contrast it with the arrangements which

FIG. 2.—The paths of the reflex. A, The path of the ordinary spinal reflex. B, The path of the sympathetic reflex. (From Langdon Brown's *The Sympathetic Nervous System in Disease*.)

pertain in the voluntary. In the voluntary nervous system the motor nerve cell lies in the grey matter of the anterior horn of the spinal cord, and the nerve fibre which arises from it is medullated in structure, efferent in direction, and effector in function. How different is the orientation (if I may use the term in this sense) of the involuntary system! Here the nerve cell occupies a situation which is extracordal and usually localized in a ganglion. The cell is connected with the cord by a fibre which is medullated in structure, pre-ganglionic in position, and yet when considered on a physiological basis connector in function—a link, in other words, which con-

nects the effector cell with an intracordal station. From the ganglionic cell there passes in a peripheral direction a fibre which is non-medullated in structure, post-ganglionic in position, and effector in function. This is a contrast appreciation of the position which I have found most helpful in my own estimation of the relations of these two divisions of the nervous system.

SYMPATHETIC AND PARASYMPATHETIC DIVISIONS.

The physiologist and the anatomist have subdivided the involuntary nervous system into the *sympathetic* and the *parasympathetic* groups, and, in view of certain clinical facts which I shall discuss later, it is well that we should recognize the reasons for which the distinction has been made.

The Distinction of Position.

There is first the distinction of position. The fibres which constitute the sympathetic division leave the spinal cord over a wide level—a level which extends from the first dorsal root to the fourth lumbar root. In contrast to this the parasympathetic outflow lies in relation to the extremities of the cerebro-spinal axis, for its impulses are transmitted from the mid-brain and the medulla through the medium of the oculomotor, the chorda tympani, and the vagus, and from the sacral segments through the pelvic nerves. "Bulbo-sacral" is the term which is sometimes applied to the parasympathetic division, and the description is a convenient one so far as anatomical distribution is concerned. It will be observed that the outflow of the sympathetic nervous system is separated from the points of exit of the parasympathetic system by those areas of the spinal cord which contain the cord innervation centres for the upper and lower limbs—the cervico-dorsal enlargement separates the sympathetic from the bulbar parasympathetic while the lumbo-sacral enlargement exists between the sympathetic and the sacral parasympathetic.

In passing we may note that this orientation of the various portions of the nervous system is of great interest to the phylogenetist and the morphologist, for it is in some respects an indication of the progress of evolution. The development of the extremities and the spinal nerve cell arrangements which their innervation demanded have evidently been later in their formation than the involuntary nervous system, hence the separation of the involuntary segments by the limb related enlargements of the cord.

The Distinction in Function.

Of greater practical importance in our subject, however, is the distinction in function which characterizes the two divisions of the involuntary nervous system. Every student of physiology knows how impressive is the distinction where the heart muscle is concerned between the action of the vagus (parasympathetic) on the one hand and the sympathetic on the other—the one inhibitory and retarding, the other accelerating. Where the enteral or alimentary system is concerned the generalization may be made that the two portions of the involuntary nervous system are to some extent antagonistic the one to the other. If the stimulus of one division results in contraction it follows almost as a matter of course that the activation of the other will induce an inhibition which is virtually a relaxation. It is true that in certain situations a single type of supply, either parasympathetic or sympathetic, is provided, and in such an event it follows that both varieties of impulse are converged by the same channel. Such an arrangement probably applies in the oesophagus and cardiac portions of the stomach, where the parasympathetic is the sole source of supply, and probably in certain sections of the large intestine where the sympathetic is the sole distribution. These facts, however, do not affect the

FIG. 3.—The cell stations of the autonomic nervous system. (From Lyle and De Souza's *Physiology*.)

* Delivered before a meeting of the City Division at St. Bartholomew's Hospital, November, 1925.

general consideration that the functions of the two divisions of the involuntary nervous system are antagonistic, and that in health the related exercise of the two types of function is so carefully balanced and adjusted that healthy tone results. I would add that, while the exercise of antagonistic function is general, it is exercised particularly in those regions in which special arrangements of muscular fibres exist—as, for example, in the region of the sphincters of the alimentary canal.

The Distinction of Distribution.

At first sight it would appear as though a distinction existed on the basis of the structural arrangements of the two divisions, and in certain respects this is true. The scheme of the involuntary nervous system is a medullated fibre from the cerebro-spinal axis, a relay ganglion around the cells of which the medullated fibre synapses, and a non-medullated fibre which is continued to the effector organ. The principle of this arrangement is maintained throughout the entire system, and exceptions which appear to exist are more apparent than real. It would seem as though the arrangement of such a parasympathetic nerve as the vagus differs very materially from the average sympathetic fibre, but such is not actually the case—both are arranged and distributed on a common scheme.

It is, I believe, correct to summarize the position as follows. It is characteristic of the sympathetic division to possess a short pre-ganglionic non-medullated fibre and a long post-ganglionic medullated fibre; it is typical of the parasympathetic, on the other hand, to show a long pre-ganglionic fibre and a short post-ganglionic distribution. The ganglion with its cell station is common to both; the distinction, if one may call it so, is in the respective lengths of the pre-ganglionic and post-ganglionic fibres. It is correct, however, to recognize that the effect of this arrangement results in a distinction, for the proximity of the parasympathetic cell station to its organ results in a localized response, while the stimulus of a pre-ganglionic sympathetic fibre is followed by a wide and diffuse reaction.

A Physiological Distinction.

One distinction there is, physiological in type, but a distinction which may have great importance in its influence upon certain chemical and pathological questions. I allude to the close and peculiar relation which the sympathetic division of the involuntary nervous system bears to the adrenals. Phylogenetically, embryologically, and functionally the two are in the closest relation to each other, and interaction of their respective functions must be constantly in evidence. In explanation of this point I quote the words of Gaskell:

"The evidence of embryology and comparative anatomy thus points strongly to the conclusion that the sympathetic nervous system arose from nerve cells containing adrenaline . . . and that when these cells left the central nervous system to become peripheral they left not as single cells, but as two separate cells, one of which contained all the adrenaline and formed the chromaffin system, and the other the nerve cells of the sympathetic system of the vertebrates."

In this we find the explanation of the fact that the nerves of the suprarenal are pre-ganglionic in type, and it makes clear Langley's generalization that the effect of adrenaline on a tissue is similar to a stimulation of its sympathetic nerves. As Langdon Brown expresses it, "the chromaffin cell represents the excitator element."

Psychological and Metabolic Distinctions.

There are yet further distinctions. It is possible to recognize a psychological difference, for the sympathetic is a medium by which the defence mechanism of the body is stimulated while the parasympathetic is the "lotus-eater's friend." Even on a metabolic basis a distinction may be drawn, for the sympathetic is as strongly katabolic in its effects as the parasympathetic is anabolic.

It will be agreed that the distinctions are sufficiently numerous and manifest to justify the subdivision of the involuntary nervous system into two groups—sympathetic on the one hand and parasympathetic on the other.

AN ASPECT OF THE EVOLUTION OF THE INVOLUNTARY NERVOUS SYSTEM.

I confess that it is with some measure of trepidation that I include this aspect of the subject. It may seem scarcely germane to the question under discussion, though I believe I shall be able to dissipate that attitude; my anxiety is rather in embarking upon a subject which remains so controversial. But the lessons I wish to draw are very simple; hypotheses I will undertake to avoid. The principle I desire to follow is one which I believe might well be applied in much of our work—the principle of thinking biologically and of correlating the lessons of biology to the problems of our clinical studies.

In a general sense it is true to state that our nervous system is composed of three elements—receptor, effector, and that important link which connects the two and in one sense makes life possible, the adjustor or connector fibre. The complexity of this arrangement is the result of a long process of evolution, and it is the phases of this process and the lessons I would draw from it that I desire to present.

Let us consider the nervous mechanism of such a simple organism as the sea sponge. A single sponge is a goblet-shaped or finger-shaped animal attached by its base to the sea bed. The ordinary bath sponge is an example of the principle which Fabre has so vividly described, the "community" grouping of the simple types of the natural world, for it is composed of a number of individual finger sponges fused together; it is, in fact, a communistic or gregarious production. The outer surface of the creature is perforated by a series of pores which lead into a system of canals each lined by "lash" cells, the function of which is to propel the water through the canals into a large space in the centre of the sponge, from which the fluid ultimately escapes by a single large opening at the unattached end of the animal. From the current of fluid in circulation the creature extracts the necessary nourishment, and the production and the control of this current are the essential features of its existence. The direction and the degree of the current are controlled by such simple arrangements as a slight contraction and bending of the body as a whole, by the formation of protoplasmic membranes which temporarily close the openings, and by the action of layers of simple muscle cells which surround the pores and the exit openings.

The mechanism is simple, but is none the less vital to the well-being and existence of the individual, and we naturally ask ourselves how it is induced and controlled. The experimental and biological knowledge which we possess has failed to reveal any evidence of nerve mechanism or transmission. The responses are put into operation by direct stimulation without any associated nervous impulse; in fact, the life of the creature is maintained by structures which respond only to direct stimulation, a local response to a local stimulus.

Let us pass higher in the scale of animal life and consider the arrangements which exist in the sea-anemone (*Actinia mesembryanthemum*). The appearance of this creature is well known. The sac-like body is attached by means of the "pedal disc" to rock or stone; the large central cavity, surrounded by its fringe of tentacles, is the space in which digestion proceeds and from which undigested residue is discharged to the exterior. When an expanded sea-anemone is stimulated by contact it responds by a general contraction of its body musculature, and the response follows a stimulus applied to any portion of the body wall. A general and collective response succeeds a local stimulus, a result which is ensured through the medium of a nerve net spreading throughout the body substance, bringing any and every portion of its body surface into association with its entire musculature. The arrangement is an example of direct transference from receptor to effector through the medium of a nerve net, the control organ or adjustor being absent.

It is in the earthworms (Annelida) that the first evidence of an adjustor mechanism becomes apparent. In the anterior extremity of the creature on the dorsal aspect there is a small collection of nervous matter which may be termed a brain, while connected with this and extending along the ventral mid-line is a segmented chain of ganglionic enlargements. Primitive in its arrangement such a central nervous system may be, and yet a very real advance

in the evolutionary trail, for it contains the internuncial neurones which constitute the beginnings of the adjustor or connector mechanism.

In the scheme of evolution muscle first functioned as an independent effector; receptors or triggers for activating the muscles were afterwards developed, the diffuse nerve net acting as the organ of transmission and intercommunication; and finally a central nervous organ was evolved at the site of the adjustor or connector mechanism, a tissue or group of tissues which eventually adopted the function of modifying responses in relation to past influences until it has become a storehouse of experience and the centre of the intellectual life (Parker).

The evolutionary picture which I have drawn would indicate that the involuntary nervous system, and particularly that portion which is grouped as the sympathetic system, is the persistence of an earlier type. The involuntary muscle of the intestine responds to direct stimulus, as does the tissue of the sponge; many of the hollow viscera possess a nerve net which functions as does the parallel system of the sea-anemone, while the nervous system of the earthworm is arranged on a plan strikingly similar to that found in the ganglionic cord of the sympathetic nervous system of man.

If it is correct to consider the sympathetic portion of the involuntary nervous system as the eldest from the phylogenic point of view, it follows that the parasympathetic is a later acquisition, and this would seem to be indicated for several reasons: (1) from its position in relation to the extremities of the cerebro-spinal axis; (2) from its relation, in part at least, to that portion of the cerebro-spinal axis which has been a late acquisition in the phylogenic tree, the mid-brain and medulla; (3) from its great length of medullated nerve structure.

The Acquisition of Contraction and Inhibition.

It is a necessary preliminary for the thesis which I am about to present that I answer a question which may be of great importance in relation to certain pathological features. The question is: "Does the acquisition of the function of motor activity (contraction and relaxation) precede the acquisition of the function of inhibition, or is there a coincident development of both functions?" The answer I venture to give is suggested to me by the results of a simple experiment on the sea-anemone.

When the creature is fed with small particles of meat the food is collected by the tentacles and passed into the central cavity, where it is ultimately digested. If fragments of filter paper soaked in meat juice are alternated with the meat both materials are accepted indiscriminately—but not for long! After some eight or ten experiences the meat is accepted while the filter paper is rejected. Inhibition has been excited, but only as a secondary and subsidiary function. The experiment affords information which enables me to answer the question, for the evidence I have quoted suggests to me that the acquisition of motor activity precedes the acquisition of the function of inhibition.

The information is important for the substantiation of my hypothesis, but for the present it is sufficient to state my belief that in the involuntary nervous system the acquisition of contractive function precedes the inhibitory; in fact it may well be that the exercise of inhibition is at first experimental and selective, and only later becomes a regularized part of the nervous mechanism.

FIG. 4.—The distribution of the parasympathetic or bulbo-sacral (central) system. (From Pottenger's *Symptoms of Visceral Disease*.)

inhibitory on the other, I believe that the motor is the more primitive, and that in the growth and progress of any individual, the motor function takes precedence in its time of acquisition of the more selective inhibitory function.

THE DISTRIBUTION OF THE SYMPATHETIC AND PARASYMPATHETIC NERVOUS SYSTEMS IN RELATION TO FUNCTION.

Authorities differ a good deal in their descriptions of the

FIG. 5.—Schematic illustration of the double innervation of the central system. (Modified from Pottenger's *Symptoms of Visceral Disease*.)

various types of supply meet or overlap—the pylorus, the ileo-caecal junction, and the lower reaches of the large intestine.

A PATHOLOGICAL APPRECIATION.

Each system has its peculiar pathology, and in common with others there is a pathology of the involuntary nervous system—a state of affairs which differs from the normal,

distribution of the involuntary nerve supply to the respective portions of the alimentary tract, but certain general considerations are accepted (Fig. 5). The oesophagus and the cardiac portion of the stomach are supplied by the parasympathetic, both motor and inhibitory impulses being conveyed along this channel. In the pyloric half of the stomach the sympathetic first becomes evident, and from this point onwards as far as the ileo-caecal region there is a combined distribution of sympathetic and parasympathetic elements, the former motor, the latter inhibitory in its effects. The large intestine as far as the lower end of the pelvic colon is evidently the site of a pure sympathetic distribution, motor and inhibitory functions being distributed along this channel. The remaining portion of the large intestine and the rectum combine a sympathetic and a parasympathetic supply, the former being inhibitory and the latter motor. Particularly important in view of the pathology presently to be discussed are those areas where the

and by doing so results in the various symptoms and physical signs of a clinical picture.

The evolution of clinical knowledge has been, and will continue to be, along certain well defined lines. Anatomy introduces the field, experimental physiology elucidates its functions, symptoms and physical signs denote derangement of these functions, and the picture is completed by the correlation of signs and symptoms with a characteristic pathology. Where the involuntary nervous system is concerned the usual path is being followed, and we are at present in a phase where, thanks to the work of the anatomist and the physiologist, a clinical picture is shaping itself and a pathology is being sought.

That disorders of the involuntary nervous system occur is beyond dispute. In relation to the hollow viscera of the abdomen such disorders may be made manifest at the sphincters or throughout the continuity of the canal. On a hypothetical basis it is possible to conceive four types of derangement:

- (a) Abnormal stimulus of contraction (spasm).
- (b) Persistence of contraction effects (achalasia).
- (c) Persistence of inhibitory effects (atony).
- (d) Irregularity of the normal peristaltic waves (arrhythmia).

It is when we attempt to speak of the pathology that we are met by the difficulty of ignorance. I can tell you the changes which result from the derangements I have outlined (a secondary pathology if you like), but there must be something deeper—original, primary, whatever you care to call it—and it is there that my difficulty lies, because as yet we do not know with any certainty in what this primary change consists, whether it be central, ganglionic, endocrine, or peripheral.

A CLINICAL PATHOLOGY.

As a primary pathology has yet to be discovered, I am driven to consider an aspect which may be described as a clinical pathology—the evidences of disease, the various disorders of the hollow alimentary viscera which in our conception proceed from derangements of the involuntary nervous system. I search through the span of life, I pick out those conditions which at one time or another with a sufficiency of reason have been ascribed to a derangement of the involuntary nervous mechanism, and I plot out in a simple fashion the age periods at which such disturbances occur. The result is interesting.

The Age Incidence.

Within a few weeks or months after birth we meet with certain disturbances which, in the opinion of many, should be included under this heading: hypertrophies of obscure origin affecting local segments of the alimentary canal; hypertrophies occurring with unflinching regularity at the sphincteric regions of the gut (the pylorus, the ileo-caecal sphincter, and the pelvi-rectal or O'Beirne's sphincter)—conditions to which there is no parallel in the later years of life; I allude to congenital hypertrophy of the pylorus, congenital hypertrophy of the ileum, and Hirschsprung's disease. These conditions possess characteristics which justify their inclusion in a special class, and as such they are representative of the early months of life.

The second group of cases which may be considered as being related in their origin to disturbance of the involuntary nervous system appear in the period of infancy. They are distinguished by irregular and abnormal peristaltic rhythms, arrhythmias, exaggerations of a physiological action which by reason of special mechanical conditions gives rise to serious pathological pictures; I allude to the intussusceptions, conditions which Neulinger once described as "uneducated and misguided types of peristalsis," clinical entities of a peculiar type and sufficiently distinctive of a definite age period in the span of life—the period of infancy.

Then follows a phase which extends from the end of infancy to puberty and into the age of adolescence, a phase of life which is remarkably free from the disturbances we have under consideration. Hypertrophies are unknown, the arrhythmias of intussusception are so rare as to be negligible events, and the atonies, the spasms, and the achalias of which I shall speak in a moment have not as yet become manifest. In figurative language it is a period of calm, and, I may add, a calm which precedes the storm, for from

the passing of puberty and the early years of the twenties up to middle life, and particularly the menopause of the female, the incidence of what one may call functional disturbances of the hollow viscera—the spasms, atonies, and achalias—are unusually frequent. It is a period of functional disturbances, of errors which are rarely serious unless it be from a functional or mental point of view, of disturbances in which a primary pathology is difficult to demonstrate, yet in which a real symptomatology is manifest. In contrast, the later decades of life are remarkably free from disturbances, and so the story ends.

The periodicity of events is surely not without significance: the hypertrophies which distinguish the early months, the arrhythmias, the uneducated functions of the early years, the period of calm as though the lesson had been learnt and an adjustment secured, the functional derangement which succeeds adolescence, the freedom from symptoms of the later years.

Let me now consider in a more individual sense the various disturbances which may reasonably be ascribed to influences exerted by the involuntary nervous system. I shall express as far as I am able the impressions which I have of the origin and nature of the various diseases, always in the light of what I have already somewhat generally described.

THE HYPERTROPHIES OF INFANCY.

Congenital Hypertrophy of the Pylorus.

The distinctive features of this condition are well known. The essential lesion is a hypertrophy of the muscular coats of the pyloric canal and antrum and to a slight degree the distal portion of the body of the stomach. The circular fibres of the pyloric sphincter are not affected, and it is a correct summary of the affected area to say that it involves that portion of the stomach musculature which is concerned with the expulsion of contents. Such changes as dilatation of the stomach, catarrh of its mucous lining, and body wasting are obviously secondary features.

The abnormality in function of an organ so affected becomes apparent on x-ray examination. There is an ill timed and abnormal, yet forcible and prolonged, contraction of the stomach muscle, and, because of the very inopportune of the function, contents are prevented from leaving the stomach.

The problem has been to account for the muscular hypertrophy. The theory of the congenital redundancy of growth, as suggested by Hirschsprung, Cantley, and others, finds few supporters, and the view which Thomson first enunciated, "that the muscle is hypertrophied because from an early period in its development it has been worried into overgrowth by constantly recurring overaction such as would result from even a slight degree of habitual inco-ordination," is now in favour. It is apparent that a demonstration of the origin of the disease is, and is likely to remain, a matter of great difficulty, but there are certain facts which help us. We must bear in mind the observation so frequently made that if the body strength can be maintained these cases pass to a natural cure by a disappearance of the hypertrophy. We have the knowledge which John Hunter first gave us, and a knowledge repeatedly confirmed, that the tendency to hypertrophy as the result of repeated forcible contractions is peculiarly well marked in involuntary muscle. We have the observation, which I believe Cameron first made, that the hypertrophy does not affect the circular fibres of the true pyloric sphincter. There is no actual obstruction—a truth which may be confirmed at operation—and it is probably significant that the change occurs at a situation in which a pure parasympathetic nerve supply merges into an area in which a mixed sympathetic and parasympathetic supply exists. Such a combination of events and related conditions suggests a persistence of motor function without the beneficial influence of inhibition, with, it may be, an achalasia or want of relaxation of the circular tissue of the pyloric ring. But my case is not yet complete.

Hypertrophic Iliac Obstruction.

During the thirteen years I was privileged to act as a member of the staff of the Edinburgh Royal Hospital for Sick Children I operated on three obscure and interesting

cases of intestinal obstruction in babies. The history in each case was somewhat similar. At birth the child appeared to be well and meconium was passed, but at a period which varied from four days to three weeks after birth signs of obstruction developed. There was vomiting of bile-stained fluid; the bowels, which had always been constipated, now ceased to act, and the abdomen became distended, a ladder pattern of small intestine being apparent. Repeated enemata usually succeeded in evacuating small amounts of bile-stained faecal matter of a somewhat inspissated type.

Laparotomy showed coils of dilated small intestine, but the lower six inches or thereabouts of the ileum was the site of a most marked hypertrophy, so marked, indeed, that in the first case I saw I mistook the condition for a hypertrophic type of small intestine tuberculosis, though I confess I was at a loss to explain how the infection could have arisen in a child of such tender age. In the two subsequent cases I recognized that the condition was a muscular hypertrophy proceeding from some obscure cause.

In the first case an ileostomy was done—unfortunately, as I now recognize, for the child succumbed—while in the other instances the abdomen was closed and recovery ultimately ensued, though constipation remained a difficulty.

I believe that these cases were examples of a disease similar in pathology and in origin to congenital hypertrophy of the pylorus. Again, it is significant that the lesion occurred where the parasympathetic nerve distribution probably ends and a pure sympathetic supply is continued; as in the pylorus, the segment affected is that immediately proximal to the actual sphincters, and there is the same tendency towards spontaneous recovery. The evidence suggests that we are dealing with the result of a neuro-muscular error, an hypertrophy which has proceeded from uncontrolled contractive impulses in a segment of bowel the muscle of which has not yet acquired the function of inhibition.

Congenital Hypertrophy and Dilatation of the Colon.

Ammon first described the condition in 1842, but the classical account which Hirschsprung gave in 1886 has led us to associate his name with the disease. Its characteristics are dilatation of the colon, most marked at the distal portion and diminishing as the gut is traced centrally, hypertrophy of the muscular coats, both circular and longitudinal, and of the muscularis mucosae. The peritoneum and mesocolon are thickened, and the associated blood vessels, lymphatics, and lymphatic glands are enlarged, and in a well established case the mucous membrane is thickened and often ulcerated. Many of these appearances, however, are secondary in their incidence, and those who have had an opportunity of seeing such cases in babies in the early stages of their development agree that hypertrophy of the muscular coat and dilatation of the colon canal are the original and the primary features. The lower limit of the change is usually at the junction of pelvic colon and rectum (O'Beirne's sphincter), but in a few instances the hypertrophy and dilatation extend downwards to the level of the anal sphincter.

I believe that the condition is of a similar nature to those I have already mentioned. Occurring at a situation where a sympathetic nerve supply comes into contact with a muscular tissue provided with parasympathetic innervation, affecting a segment of gut on the proximal side of a sphincter, associated with hypertrophy of the muscular fibres (though in this instance the gas content of the large bowel produces a coincident dilatation), the disease first becoming evident in the weeks which immediately succeed birth, this combination of circumstances suggests an etiology similar to that of congenital hypertrophy of the pylorus and congenital hypertrophy of the ileum—an uncontrolled contractive function, a delay in the acquisition of the power of inhibition, combined, it may be, with achalasia, an insufficient relaxation of the associated sphincters.

There remains yet another example of an hypertrophy of the alimentary tract ascribable to the influence of the involuntary nervous system—the condition of cardiospasm,

a dilatation of the lower end of the oesophagus with hypertrophy of its walls. I believe that this disease might with reason be included. Fleiner¹ has described examples occurring so early in life that he classified them as congenital; hypertrophy and dilatation characterizing the local pathology, and it may be that one of the nerve junctions which distinguish the disorders I have already described exists here also, for our knowledge of the nerve distribution of the oesophagus is by no means exact. There are, however, aspects in which cardiospasm differs from the aforementioned hypertrophies and dilatations, and therefore I provisionally exclude it. In relation to the other conditions, however, the point I wish to make is that in the early weeks and months of life we find highly distinctive derangements of the non-striated muscle of the alimentary tract, which are characterized by hypertrophy, which occur in situations where different types of nerve supply intermingle, which under certain conditions eventually undergo restoration to normal, and which are without parallel in the later years of life. It has seemed to me that the process which explains these errors is one which in its beginnings is functional, a delay in the acquisition of the power of inhibition by certain segments of the alimentary canal, segments which are proximal to sphincters and which correspond to areas of different nerve type junction.

As I have recalled in the simple experiment of feeding the sea-anemone, the acquisition of inhibition lags behind the functions of contraction and relaxation, and in the disease which we have under review it may well be that an undue delay in the appearance of the function of inhibition will explain the peculiar pathology, an hypertrophy which results from an uncontrolled contraction and relaxation. With the acquisition of the function of inhibition the stimulus is controlled and the hypertrophy disappears.

THE ARRHYTHMIAS OF EARLY CHILDHOOD.

While the distinctive feature of involuntary nerve errors of the early weeks and months of life is localized hypertrophy, the derangements of a later period are characterized by an exaggeration of the normal functions of the muscular coats—the function of peristalsis—and as a result we find that during a period which extends roughly from the sixth month to the end of the second year, intussusceptions, the results of an excessive and misguided peristalsis, are met with. In the last 500 cases of intussusception operated on in the Edinburgh Children's Hospital 295 had their beginnings in the small intestine, in the lower end of the ileum, where after reduction the original point of invagination remained apparent. Now the muscle of the small intestine demonstrates three varieties of activity:

(a) *A Segmentation Movement.*—An example of a local response to stretching by contents, and one independent of the myenteric reflex. The aim of this movement is to break up masses of food and to bring the nutritive material into close association with the absorptive mucosa of the gut. Because of it food passes up and down the gut for a few centimetres only.

(b) *True Peristalsis (Diastalsis).*—In this instance the stimulus is chemical rather than mechanical, and a wave of inhibition always precedes the contraction, which moreover invariably progresses in the distal direction. This movement depends upon the integrity of the nerve net, for, if repeated encircling incisions be made through the musculature of the small intestine so as to interfere with the function of the myenteric nerve plexus lying between the muscular coats, the movement is abolished. The function of this type of peristalsis is to pass the nutritive material on for some considerable distance in order that fresh areas of absorption and digestion may be reached.

(c) *The Peristaltic Rush.*—Under certain conditions the true peristaltic wave may advance at a very rapid rate. This is called "the peristaltic rush," and it is evidently in this way that intussusception is induced. It is a swift wave of peristalsis, which may sweep over the entire length of the small intestine in about one minute, and it was first observed by Van Braam-Houckgeest in rabbits killed by asphyxia. The confused squirming of the coils as the contraction rushes along has caused the phenomenon to be designated the "Rollbewegung," or the vermicular wave.

That the rushing wave is actually peristaltic in character was proved by the observations of Snelitzer and Aner. They showed that it consists of a contraction preceded by a completely relaxed section of the gut, and they were able to evoke the phenomenon in rabbits by intravenous injection of a combination of substances designed to

produce simultaneously stimulation and inhibition of intestinal activity. The most effective pair was ergot (stimulant) and calcium chloride (depressant).

When the phenomenon occurs in man the wave is carried with some degree of violence throughout the length of the small intestine. As long as inhibition precedes contraction no harm results, but when the wave reaches the lower end of the ileum, an area in which a new type of nerve supply is encountered, under certain conditions the preceding phase of inhibition is not transmitted, with the result that the strong contraction of the "peristaltic rush" carries a circular area of the gut into the distal segment as an invagination, and the intussusception has begun. I said that the event was likely to occur only under certain conditions, for every child who evidences the "peristaltic rush" does not develop intussusception; a developmental anomaly is the predisposing feature, for, if the ileo-caecal segment has failed to complete its fixation to the posterior abdominal wall, if, in other words, the third stage of intestinal rotation has not been completed, and the ileo-caecal segment is provided with a loose mesenteric attachment, the occurrence of a peristaltic rush is likely to be followed by the development of intussusception. Why this should be is difficult to explain. The laxity of the attachment offers a mechanical explanation of the migration of the intussuscepting segment, but in all likelihood there is a further influence which concerns the nerve supply of the bowel, and it may be the nodal tissue in the ileo-caecal segment.

It is natural that we should inquire about the origin of the peristaltic rush. In view of the experimental work of Snelzer and Auer we are tempted to imagine that some dietetic error which combines the depressant and the stimulant factors may be the source, but, even so, the original stimulus, whatever it may be, is acting upon an intestine which in some way is predisposed to disturbance of this nature, a bowel the functional education of which is not yet adjusted and stabilized.

The period of the intussusceptions is followed by an interval which is largely free from involuntary nerve disturbance of the alimentary tract. It would seem as though the lesson had been learnt, adjustments made when necessary, and the functional education completed.

THE DISORDERS OF ADULT LIFE.

With the passing of puberty, however, or later it may be, in certain individuals there is another breakdown in the neuro-muscular alimentary arrangements, not immediately serious as are the hypertrophies of the early months and the arrhythmias of the early years, yet ultimately of great importance from various points of view, psychological, diagnostic, and toxicæmic. The disturbances of these later years are most elusive in both their etiology and their pathology. In view of the time period of their manifestation and the response which many cases show to glandular therapy it may well be that a derangement of the glands of the internal secretories is the origin of the nervous disturbance. From what I have seen I am convinced that an imperfect attachment of the caecum and ascending colon to the posterior abdominal wall is a frequent, in fact I would say a constant, accompaniment of the functional disorders—that, in other words, an abnormal type of intestinal arrangement exists to make such disturbance possible. But we must confess that our knowledge of the etiology remains largely hypothetical.

The pathology is as difficult of demonstration as the etiology. Spasms of achalasia or want of relaxation and atonies express the changes which give rise to symptoms, yet, except in the case of the atonies, many of them are as transient as the morning mist: they vanish during anaesthesia and operation, and when life has fled they too have vanished.

But it is in respect of diagnosis that a great interest lies. During six months' work in the Edinburgh Royal Infirmary I have kept a careful record of fifty-eight cases sent to hospital with the diagnosis of appendicitis. Twenty-four of these showed pathological conditions of the appendix, thirty-four were examples of ileo-caecal pain certainly, but the explanation was not an inflammatory lesion of the appendix, but a spasm of the caecum and the

related colon. There was a diagnostic error which exceeded 50 per cent.

I can produce similar figures in relation to the stomach, where gastric and pyloric spasm and achalasia of the pyloric sphincters have closely simulated stomach and duodenal disease. It is true that many of these disturbances are reflex, and in some instances the association is obvious, but in many it is impossible to discover the source from which the derangement is proceeding. Pain and functional derangements are the usual symptomatic evidences of the spasms and the achalias. Gastric spasm and achalasia of the pylorus may closely simulate the symptomatology of serious stomach disease. I have alluded to the frequency with which ileo-caecal and ileo-colic spasm are confused with appendicitis. I have seen a spasmodic contraction of the colon so closely simulate organic colon obstruction that only a laparotomy made the diagnosis clear. In fact, we can rarely afford to neglect the possibility of a functional disorder of the involuntary nervous system simulating the more serious organic lesion.

The atonies constitute a surgical problem of great difficulty, whether they affect stomach, small intestine, or colon. It is unusual to find associated pain, though a painful spasm may occasionally be superadded to the existing atony. It is rather in the functional derangement that the seriousness lies, for it is inevitable that there is delay in the passage of contents, and the results of toxic absorption are therefore superadded to complicate and obscure the original picture.

It is with a purpose that I have avoided any reference to problems of treatment; it has rather been my intention to present to you a general aspect of the disorders of the involuntary nervous system as met with in the intestinal tract, and to attempt to trace what may be described as an evolutionary picture of disease.

REFERENCE.

RADIO-DIATHERMY IN THE TREATMENT OF INOPERABLE MALIGNANT DISEASE OF THE UPPER AIR AND FOOD PASSAGES.*

BY

SIR WILLIAM MILLIGAN, M.D.,

CONSULTING AURIST AND LARYNGOLOGIST TO THE ROYAL INFIRMARY,
MANCHESTER; SURGEON LARYNGOLOGIST TO THE MANCHESTER
RADIUM INSTITUTION.

THE early recognition of malignant disease and its immediate removal by the knife is a counsel of perfection not always attainable. Procrastination is unfortunately inherent in human nature, while other factors, such as fear of operation and the dread of being informed of what actually is wrong, act as deterrents in preventing many patients from seeking advice at that stage when a cancerous growth or ulcer is a strictly localized process and therefore curable.

In my opinion the dissemination of knowledge amongst the public concerning the early symptoms of malignant disease is long overdue, even if it be given at the risk of causing unnecessary alarm to a limited section of the population. The good of the majority should be considered rather than the fears and prejudices of the minority. Educational propaganda would undoubtedly serve a useful purpose, more especially in drawing attention to the possibility of something serious being wrong, and so in gaining that all-important factor—time.

In the fourth quarterly report of the Cancer Survey of San Francisco, Hoffman draws attention to the fact that of 255 deaths of women suffering from cancer of the breast 107 were not operated upon, owing, in all probability, to their having gone to hospital too late, while of 319 deaths from cancer of the uterus 156 were deemed inoperable for similar reasons. The view, so widespread and deep-rooted, that cancer is a disease of later life is mischievous and erroneous, as out of 493 deaths from cancer of the stomach

* A paper read before the Nottingham Medico-Chirurgical Society, January 21st, 1926.

among males the youngest occurred at the age of 23, the oldest at 95, and out of the 255 deaths from cancer of the breast the youngest occurred at the age of 27, the oldest at 85.

When, owing to the situation, size, and extent of a malignant growth, surgical proceedings are contraindicated, great relief, and in a certain proportion of cases apparent cure, may be effected by the employment of surgical diathermy, by the use of radium, or by a combination of these two methods—in other words, by radio-diathermy.

The destruction of the local growth or ulcerated area is naturally the first step in treatment, but equally important is the prevention of cell implantation, so common during surgical manipulations, and the sealing up of the lymphatic tributaries which run into neighbouring glands. In diathermy, or, as it is sometimes called, endothermy or "through-heating," we have a method of attack of great practical importance and utility, in effecting as it does the destruction of a malignant growth by coagulation.

Diathermy, like any other therapeutic agent, has its limitations, and is contraindicated in the case of large adherent growths, growths in the intestinal tract, and when there is marked cachexia. The principle underlying treatment by diathermy or "cold cauterization" is that the tissues against which the active electrode is placed resist the entrance of the high frequency current, a current capable of reversing itself from 500,000 to 1,000,000 times per second, with the result that a degree of heat is generated sufficient to cause complete tissue necrosis. Small and accessible growths are in this way readily destroyed, large growths only as the result of repeated applications.

Many years ago Professor d'Arsonval showed that a high frequency current of 3 amperes could be passed through the body with the production of no other sensation than that of heat, while Nagelschmidt turned the "heating through" of the tissues to practical account in both medical and surgical manipulations. The coagulation of the primary growth is attended frequently by great relief, by freedom from pain and haemorrhage, and serves often to prolong the patient's life in comparative comfort.

In many cases it is possible, by means of a block dissection, to remove all infected glands, and by subsequent irradiation to secure the sealing up of the lymphatic tributaries in the dangerous zone, with the result that what was surgically an inoperable growth becomes an operable possibility. The less the biological involvement of the cell the greater its sensibility. Malignant cells, possessing as they do a lower vitality than the normal cells of the body, are comparatively easily destroyed by coagulation, just as they are also by the beta and gamma rays of radium, hence a combination of the two methods is peculiarly valuable when the pathological area is of considerable dimensions. Speaking generally, the depth of tissue coagulated by any single diathermy application is equal to the diameter of the end-piece used, whether disc or button. When, however, applicators having spikes attached are employed, coagulation extends somewhat deeper, more especially if the tissues are kept moist with a 10 per cent. saline solution.

The great advantage of diathermy over electro-cauterization is that in the former the zone of destructive influence is wide, whereas in the latter it is limited by the formation of a carbon core. The type of active electrode used varies with the size and situation of the growth. Button or disc-shaped electrodes are useful where the growth is large and accessible, the needle electrode when it is small, and electrodes with from three to six prongs when it is of the penetrating and infiltrating type. Knife or saw-shaped electrodes are used by some operators when the growth is one suitable for excision. The indifferent electrode should be a plate of metal 6 to 8 inches square covered with a thick towel or twenty layers of lint soaked in 10 per cent. salt solution, and firmly and evenly fixed to the chest wall, the arm, or the leg by means of a bandage.

To ensure the greatest amount of coagulation the active electrode should be applied firmly to the tissues, and applied cold. The current should then be turned on slowly and allowed to attain its maximum intensity (1 to 2 amperes) in the space of from thirty to forty seconds.

The immediate effect is blanching of the tissues around the terminal, due to the coagulation of their albuminous constituents, followed by bubbles of steam escaping from the burned and now dry area. To obviate steaming and consequent scalding of adjacent tissue the part should be kept moist with saline solution, as when active sparking takes place the diathermy action practically ceases. After the growth has been carefully treated with the active electrode the coagulated tissue should be gently scraped away and the active electrode again applied to the next layer of morbid tissue. In this way the whole growth and the zone of tissue surrounding it is gradually coagulated and got rid of.

The time taken to coagulate and remove a growth will vary with its size and accessibility, but no one application should exceed twenty to twenty-five minutes. The amount of shock following diathermy is practically negligible, and any rise of temperature is seldom more than from one to two degrees, while pain is rarely complained of. The slough resulting from the application takes from ten days to a fortnight to separate; during which time the part should be kept as clean as possible by spraying with hydrogen peroxide. Dusting with powdered charcoal is useful in keeping down the very disagreeable fetor which is so often noticed during the sloughing process.

The effect of diathermy is to sterilize the tissues, and although sepsis may, and does, supervene, it does not do so before a protective barrier has been set up. The resulting scar is soft and pliable and does not form adhesions to surrounding tissues. When coagulation is performed in the neighbourhood of bone, necrosis is practically certain to result, and sequestra may take months to separate.

While the density of the current is sufficient to coagulate fixed tissues and blood circulating in capillaries and small blood vessels, it is quite insufficient to cause coagulation in larger vessels—for example, the lingual artery—with the result that as sloughing takes place subsequently the walls of adjacent blood vessels may give way and severe secondary haemorrhage ensue.

The most brilliant and most lasting results are to be obtained in electro-coagulation of malignant growths or areas of ulceration in the upper pharyngeal cavity—for example, the palate, tonsils, and the base of the tongue. Malignant disease of the palate—from the surgical point of view always very unfavourable—is specially amenable to treatment by the diathermy button, being readily accessible and seldom complicated with glandular involvement. In dealing with such cases free excision or destruction of tissue is essential, regardless of any possible and subsequent deformity.

To estimate the exact extent of infiltration is impossible, and in order to destroy any outposts of disease or, in other words, the zone of attenuated malignancy, it is necessary to coagulate for, if possible, half an inch or thereabout beyond the margins of obvious disease. This often leads to a certain amount of deformity, which later on, however, may be repaired by some form of plastic operation or by the use of some artificial appliance.

The results of electro-coagulation in such cases are frequently brilliant, as is evident from the history of the following case.

H. W., aged 52, consulted his local doctor on account of pain in swallowing, severe and frequently repeated attacks of haemorrhage, and constant pain in his ear. For years he had been a heavy smoker and a heavy drinker of brandy. On examination the left side of the soft palate was seen to be occupied by a large fungating and very vascular ulceration extending beyond the middle line and spreading forwards over the hard palate, with the clinical appearances of an epithelioma, subsequently confirmed by microscopic examination. The affected area was submitted to diathermy treatment and completely removed. Considerable cicatricial contraction resulted, but not sufficient to render the wearing of an obturator necessary. Complete healing took place, with a firm cicatrix. For five and a half years the patient led a normal life; he then again came under observation, complaining of dysphagia. No recurrence of the original disease had taken place, but a new malignant growth was found involving the right arytenoid region and extending along the right ary-epiglottic fold.

Cancer of the floor of the mouth is peculiarly amenable to diathermy, care being taken to coagulate freely around the growth until all indurated tissue has been destroyed.

Malignant growths involving the tonsil and palatine

arches and frequently invading the base of the tongue are by no means uncommon, and from the surgical point of view are more frequently inoperable than operable. In such cases there is almost invariably a considerable amount of infiltration and fixation, with extensive glandular involvement in the superior carotid triangle. Owing to the fact that epithelial growths in this situation are very radio-resistant a combination of diathermy and irradiation is useful, the infected glands being first removed after ligation of the external carotid artery, followed ten days to a fortnight afterwards by ligation of the other external carotid artery and coagulation of the primary seat of disease.

Ligation of the external carotid artery is valuable because (1) it makes removal of the glands an almost bloodless operation, and (2) it depletes the primary growth of blood. To obtain free access to the malignant growth and effect complete removal of enlarged glands may necessitate a subperiosteal resection of the angle of the inferior maxilla. By so doing the growth is made accessible, and may be treated from the inside by coagulation and from the outside by irradiation.

If ultimate success is to be obtained it can only be by employing heroic measures. Such cases are surgically inoperable, are invariably complicated with extensive glandular involvement, and even if the primary growth is successfully diathermized the disease will rapidly reappear unless the lymphatic field is thoroughly drenched with the gamma rays of radium.

Irradiation may be effected either by burying needles along the route of the lymphatic stream leading from the focus of disease, by means of applicators applied around the angle of the jaw, or by a combination of both methods. The results are at times surprisingly good, several of the writer's patients having had complete freedom from symptoms for periods of from three to five years.

LARYNGEAL GROWTHS.

Laryngeal cancer fortunately tends to remain localized for a considerable time, and if diagnosed and operated upon at once affords encouraging results. Unfortunately, from one cause or another an early diagnosis is by no means always made, the psychological moment for active intervention passes, and the case is relegated to the arena of the surgically inoperable. This applies especially to cases of extrinsic origin, whose early progress is often unfortunately painless—I say painless advisedly—and symptomless until the presence of enlarged glands in the neck calls attention to something being wrong. In purely intrinsic cases the early loss of voice, hoarseness or huskiness, acts as a most useful danger signal, as glandular involvement is a very late phenomenon, if it occurs at all.

From a surgical point of view the operative treatment of extrinsic laryngeal cancer is often very disappointing, the necessary mutilation of tissue and loss of function being as alarming to the patient as was the original disease.

Access to a laryngeal growth may be obtained *per vias naturales*, with or without the aid of suspension laryngoscopy or after the performance of a laryngo-fissure. The position of the growth, its size and its anatomical relations, help to determine the particular route of approach. I venture to advocate the more frequent performance of a laryngo-fissure, for the reason that so many growths, both extrinsic and intrinsic, are thereby rendered so much more visible than even when approached through the mouth. Certain extrinsic growths—for example, those springing from the sinus pyriformis, the arytenoid region, and the epiglottis—are, however, particularly suitable for suspension approach, more especially if the patient happens to possess a long thin neck and good teeth. A preliminary tracheotomy should be performed whichever method of approach is adopted, as the effect of electro-coagulation is to produce a marked oedema of the loose cellular tissue of the larynx with consequent risk of asphyxiation.

In the event of glandular enlargement being present, the question arises whether the glands or the primary growth should be attacked first. I am of opinion that the glands should be removed in the first instance, after ligation of the external carotid artery, with the proviso that when

glands are fixed and adherent to the deeper structures, carotid artery, jugular vein, and other pre-vertebral structures, operation should not be proceeded with. There is a very distinct limit, often overlooked, to what electro-coagulation and radium treatment is capable of accomplishing, and these limitations should be recognized. Where glands are, however, non-adherent and can be removed, the lymphatic avenues leading to them should be thoroughly irradiated after coagulation of the primary growth. This is best effected by the insertion of from six to eight tubes, containing from 5 to 10 mg. of radium, along the course of the lymphatic stream. I am now fully persuaded that better results are obtained by implanting radium needles within the tissues than by applying applicators on the surface, the number of milligram hours varying with the extent of the existing disease.

When, however, it is decided to rely on radium alone, a useful plan is to resect a portion or the whole of the thyroid ala and through the fenestration to insert with precision into the growth a varying number of tubes and subsequently to fix a casted radium applicator round the neck.

MALIGNANT GROWTHS OF THE ANTRUM AND ETHMOIDAL LABYRINTH.

The malignancy of antral and ethmoidal growths varies enormously, some running a very virulent course, others, although pathologically malignant, being clinically almost benign. The lymphatic tributaries leading from the antro-ethmoidal region run to the submastoid and carotid glands, which, at a late stage, tend to become much enlarged. In the event of the disease being so advanced as to preclude the advisability of a resection of the upper jaw or its removal by means of a lateral rhinotomy, it may be coagulated and irradiated after exposure. Exposure of the growth is advisable to facilitate the free application of the active electrode, and to minimize subsequent necrosis.

After resection of the anterior wall of the maxillary sinus or opening up of the ethmoidal labyrinth, as much as possible of the growth should be removed with a curette and the cavity thoroughly diathermized with a button or disc-shaped electrode. The application of radium with the aid of a face-mask should subsequently be undertaken. The steps taken in such an operation are therefore as follows:

1. Ligation of external carotid artery.
2. Removal of glands.
3. Exposure of antral or ethmoidal growth by external incision.
4. Curetting of growth.
5. Application of button electrode.
6. Surface application of radium.

Frequent inspection of the cavity should be made after operation in order to detect and to coagulate any suspicious areas.

NASOPHARYNGEAL CARCINOMA.

Malignant growths in the nasopharynx present another problem of great perplexity. Sarcomatous growths yield fairly readily to treatment by means of radium alone, the number of needles and the dosage employed varying with the size and structure of the tumour, whether round-celled or spindle-celled.

True carcinomata—spheroidal-celled, columnar-celled, or epitheliomatous—are unfortunately not so satisfactory, largely owing to the difficulties of adequate approach. Division of the soft palate with removal of a portion of the hard palate, or the slinging forward of the soft palate with rubber bands helps to expose the growth to view, and to make the application of a button or pronged electrode fairly satisfactory. There should be no hesitation in freely removing any tissue, hard or soft, in order to gain proper access to the growth. Several applications may be necessary to coagulate even a small growth owing to the mechanical difficulties involved.

Nasopharyngeal fibromata or fibrosarcomata respond well to coagulation, which probably affords the least dangerous method of attack.

ESOPHAGEAL CARCINOMA.

Of all organs in the body the most disappointing, from the surgical point of view, is probably the oesophagus. The absence of a serous coat combined with a flabby and

lax musculature renders it peculiarly unsuitable for operative procedures. Moreover, the risk of rupture of its walls from ulceration or instrumentation must not be ignored.

Cancer of the hypopharynx—in females a by no means uncommon affection—is amenable to diathermy provided the disease is high up and strictly localized, which it rarely is, however. In such cases the growth may be rendered visible with Seiffert's directoscope.

Access to a malignant growth in the oesophagus situated about the level of the bifurcation of the trachea—a common situation—or at the cardia, is naturally difficult, but is possible with the aid of the oesophagoscope. In this situation diathermy is, however, always dangerous owing to the difficulty of ascertaining the degree of mural involvement and the risks of perforation. In every case an attempt should be made to determine the extent of the tumour. This may be done by the method of "coulée reversée," the patient lying in a reclining position with the head lowermost, thus permitting the opaque meal to run backwards and so to outline the lower edge of the growth. An active electrode is then passed and the growth carefully coagulated. The electrode recently designed by Wright of Bristol renders the application of diathermy easier and safer than with any other, since it coagulates from below upwards, and therefore under the observation of the operator, instead of, as is usual with other instruments, from above downwards. If it is desired to irradiate with radium, an endless thread, to which one, two, or three screened tubes containing radium element are attached, is swallowed and the tubes pulled into position in vertical series. The preliminary coagulation and consequent opening up of the stricture will be found to permit of this being done comparatively easily. In two of my cases a lumen, sufficient to enable solid food to be swallowed was obtained, while in another case coagulation of the growth was followed by complete cicatricial atresia. In all cases the performance of a preliminary gastrostomy is advisable.

Whether it will ever be possible to excise a malignant growth of the thoracic oesophagus after the performance of a thoracotomy is in the lap of the gods. At the moment diathermic coagulation, with or without the subsequent employment of radium, affords a chance, although a very slight one, of eradicating the disease.

The early and more frequent use of the oesophagoscope in all cases with symptoms of even slight dysphagia should be impressed upon the profession as the one and only means of arriving at an exact diagnosis.

Summary of the Advantages of Diathermy.

1. That it is of definite value when ordinary surgical procedures are contraindicated.
2. That it is followed by little, if any, shock.
3. That with reasonable care it is a practically bloodless operation.
4. That besides sterilizing the tissues it blocks the vascular and lymphatic channels leading to and from the growth.
5. That by so doing it tends to prevent dissemination of the cancer cell.
6. That it affords relief from mechanical symptoms such as obstruction, dyspnoea, etc.
7. That it arrests the tendency to spontaneous hæmorrhage.
8. That it relieves pain.
9. That the resulting scar tissue is soft and pliable and does not form adhesions.
10. That septic bronchopneumonia is less frequent than after severe cutting operations.

Disadvantages of Diathermy.

1. That it destroys a certain area of healthy tissue around the original growth.
2. That the walls of blood vessels in the immediate neighbourhood of the growth may become softened and ulcerated, with resulting attacks of severe secondary hæmorrhage.
3. That when the skin is involved keloid cicatrices may develop.

The advantage of combining the application of radium with coagulation by diathermy is that the lymphatic area is thereby irradiated, wandering malignant cells are killed off, and the risk of subsequent metastasis is materially lessened.

The results obtained by radio-diathermy, complicated and tedious as the treatment undoubtedly is, will repay all the trouble taken, the patient frequently taking on a new lease of life, free from pain and hæmorrhage, and in most instances ending it with greater comfort than would otherwise have been the case.

ON THE ACTION OF CERTAIN ALLEGED INTESTINAL ANTISEPTICS.

BY

LAWRENCE P. GARROD, M.B., M.R.C.P.,

DEMONSTRATOR OF PATHOLOGY, ST. BARTHOLOMEW'S HOSPITAL.

THERE are on the market several preparations described as "intestinal antiseptics." To my mind the meaning of the advertisements can only be that the preparations are capable, when taken by the mouth, of destroying at least a proportion of the organisms in the intestinal tract. The total extent of that effect, and its degree in the case of each different type of organism present in the bowel, are not described; it may, in fact, be said that the claims made for these products are, with one exception, unsupported by any evidence, generally known, of their action in the human subject.

The flora of the bowel undergoes very radical changes between the jejunum, where organisms are first found in any considerable numbers, and the rectum.¹ The organisms found in the former situation disappear even before the ileo-caecal valve is reached, and those present in the faeces make their first appearance certainly no higher than the middle of the jejunum. What the action of an alleged intestinal antiseptic may be on the organisms in the upper part of the intestinal tract is almost impossible to ascertain, and the following observations are concerned only with those present in the faeces. These, or certain of them, are the organisms which it is regarded as desirable to destroy when an intestinal antiseptic is employed, and they are those which these drugs are generally understood to be capable of destroying.

The enumeration of living aerobic organisms in the faeces is not a difficult matter. To enumerate living anaerobes with accuracy is almost impossible, and these have therefore to be left out of account, it being assumed that the numbers of coliform bacilli and Gram-positive cocci obtained in aerobic cultures are a sufficient index to the total numbers of living organisms of all kinds in the specimen. Certain factors have, however, to be taken into account which render such an investigation less simple than would at first appear. Of these the principal is that wide variations may occur from day to day in the total numbers of living organisms in the faeces. A fluid stool may contain one hundred times as many living organisms as a scybalous stool from the same subject. It is therefore desirable that the subject of an experiment with one of these drugs should be accustomed to passing daily stools of reasonably uniform character, and further, that the observations should be continued over a considerable period, in order to obtain a reliable average. It is necessary, also, to cultivate the specimen within a few hours of its being passed, or to keep it in the cold, since rapid multiplication of the organisms contained in it will occur at room temperature. Lastly, in view of the well established effect of diet on the bacteriology of the faeces, it is desirable that the subject should remain on a fairly consistent diet throughout the experiment. These precautions were observed in the investigations to be described. The method employed was the following:

Method of Investigation.

About half a gram of faeces is placed in a large sterile tube of known weight and accurately weighed. Sufficient sterile water is added to give a convenient dilution, such as 1 in 50. Complete emulsification is carried out by forcing the fluid in and out of a long syringe with a wide-bore needle (this process will do in

two minutes what will occupy a mechanical shaker half an hour). Decimal or other convenient dilutions are then made from the emulsion, and from each of the last two, three, or four dilutions 0.1 c.cm. is sown on to large plates, previously dried thoroughly (at least 5 per cent. of the water in the medium being evaporated by standing on a 55° C. oven), and spread until the fluid sown has been absorbed by the surface of the medium, leaving it dry. After incubation the colonies are counted, and the results expressed in millions of living organisms of each type per gram of faeces.

Cultures made by this method yield uniformly spaced discrete colonies, and, apart from their value as affording quantitative results, are superior to those made by the ordinary method.

The syringe employed for emulsification and the 0.1 c.cm. pipettes for sowing had to be specially made for the purpose.

That the numerical accuracy of the results can be relied on was shown by duplicating the process, consistent results being obtained.

The procedure followed was to examine daily by this method the faeces of a subject who was either a normal individual or a patient not known to be suffering from any intestinal disorder, for a period of about a fortnight, during one-half of which the drug was administered in what are understood to be adequate doses. The results may be shown in the form of a graph, but they can most concisely be presented as the average numbers of living organisms in the faeces during the two periods. The following table shows the whole of the results obtained by experiments *in vivo*.

TABLE I.—Effect of Intestinal Antiseptics on Total Numbers of Living Organisms in Faeces.

Drug.	Dose.	Before Administration.		During Administration.		Reduction or Increase.
		Days.	Average Number of Living Organisms per Gram in Millions.	Days.	Average Number of Living Organisms per Gram in Millions.	
Dimol ...	gr. 8	21	520	14	416	-20%
Kerol ...	m 12	6	2,050	7	2,061	+0.5%
Yatren ...	0.5 gm.	7	767	5	1,450	+89%
Izal (1922) ...	m 6	10	453	7	44	-90%
Izal (1925) ...	m 6	15	690	7	632	-8%
Izal (1925) ...	m 22	7	40	6	100	+150%

The figures under "Dose" indicate the total quantity given daily. All the drugs, except yatren, were administered three or four times a day.

Of some of these results there is a good deal further to be said in explanation.

The case of dimol and of Kerol is comparatively simple; the change in numbers is so slight (in the former a decrease of 20 per cent., and in the latter an increase of 0.5 per cent.) as to afford no evidence of antiseptic action.

Yatren is a preparation the use of which is advocated in amoebic dysentery²; it claims, in fact, only to be an amoebicide, and its general antiseptic effect was only investigated because it had been supposed to exert a favourable influence on non-dysenteric ulcerative colitis. The actual increase in the number of living organisms in the stools during the administration of this drug is presumably fortuitous.

The case of izal presents a different problem. The capabilities of this preparation were investigated no less than twenty-four years ago by Gordon,³ and his findings represent the single exception referred to in the first paragraph of this article. These were confirmed, as indicated by the figures under "Izal (1922)" in the above table, which show a very great reduction in the number of living organisms in the faeces during its administration. This experiment was repeated in 1925, with entirely negative results, and again in the same year, under the strictest precautions against error which could be devised, including the carrying out of most of the cultures in duplicate throughout, and with the employment of a much larger dose of the preparation. So far from any antiseptic action being demonstrated, the total number of living organisms in the faeces was actually greater during the administration of the drug than before and after it. The purpose of this paper is to record certain results without attempting to draw any but fully warranted conclusions, and it

can therefore only be suggested that the cause of this discrepancy may perhaps be a recent change in the composition of izal; the boxes in which it is now sold are labelled "Improved Izal Perles," and if the "improvement" referred to has had the effect which these results appear to indicate it will be well for its manufacturers to revert to the original process employed in preparing it.

Granting the conclusion suggested by the above results—namely, that three well known "intestinal antiseptics" are incapable of affecting appreciably the numbers of living organisms in the faeces—it may well be asked, What are the ideal requirements for an "intestinal antiseptic," and in which respect do these preparations fail?

Assuming that such a preparation can exist, it should have the following properties:

1. It should not be decomposed by the processes of digestion.
2. It should not combine with, and be rendered inert by, any substance present in the intestinal tract.
3. It should not be absorbed by the intestinal mucous membrane.
4. It should be capable of destroying intestinal organisms even in high dilution.

That certain of these preparations fulfil the last of these requirements is claimed by their manufacturers. But it must be remembered that the usual method of titrating antiseptic power *in vitro* involves exposing a saline suspension of such an organism as *B. coli* to the unhindered action of the antiseptic, a proceeding which takes no account of the first three postulates suggested above. In which of them the truth lies as to the failure of these drugs *in vivo* it is not possible to say, but some indication may be afforded by the following experiments, in which the antiseptic power of these preparations was investigated, not on single organisms, but on the faeces themselves, *in vitro*.

A 1 in 10 emulsion of a specimen of faeces was made. From this emulsion further dilutions were prepared, and cultures sown by the method described above. Another portion of the original emulsion was mixed with an equal amount of a solution of the antiseptic to be investigated at 37° C. for one hour. Decimal dilutions were made immediately, and cultures made in the same manner.

It should be observed that none of the preparations here concerned is readily soluble in water. Izal and kerol are oily substances from which adequate emulsions in water can be prepared only with difficulty. Yatren is very sparingly soluble (its exact solubility was not determined). Dimol (of which a tablet described as containing 1 grain weighs, after removing its sugar coating, about 4 grains, so that it is presumably mixed with some other material) is not completely soluble even in the higher dilution employed. The following table indicates the results obtained.

TABLE II.—Action of Intestinal Antiseptics on Faeces *In Vitro*.

Drug	Total Number in Faeces (millions).		Total Number after 1 hour at 37° C. with Antiseptic (millions).		Reduction or Increase.	
	Streptococci.	Coliform Bacilli.	Streptococci.	Coliform Bacilli.	Streptococci.	Coliform Bacilli.
Izal (1925) 1 in 200	3.6	75	0.66	0	-82%	all killed
Izal (1925) 1 in 2,000	3.6	75	16	10	+344%	-87%
Dimol 1 in 200 ...	10.6	7.4	0.016	0	-99.6%	all killed
Pimol 1 in 2,000	10.6	7.4	10.8	1.5	+2%	-80%
Kerol 1 in 200 ..	10.6	7.4	2.7	0.0002	-75%	-99.99%
Kerol 1 in 2,000	10.6	7.4	12.4	1.46	+17%	-81%
Yatren 1 in 400...	218	3	771	2	+255%	-33%
Yatren 1 in 4,000	218	3	526	2.8	+141%	-6%

In control emulsions incubated and coliform bacilli diminished same as in the tubes containing 3 obtained after admixture with the faecal emulsion.

The interpretation of these results would appear to be as follows.

Yatren has no anti-septic effect whatever; during incubation the organisms in the emulsion multiplied. Since this

drug is claimed only to be an amoebicide, this result is what might be expected. The other three preparations exhibit a common action, varying little in degree, which is of considerable interest. They destroy all *B. coli* in a dilution of 1 in 200, and a large proportion of *B. coli* at 1 in 2,000. On the other hand, they destroy only a proportion of streptococci at 1 in 200, and at 1 in 2,000 streptococci actually multiply. This is a selective action paralleled by the well known property of phenol of inhibiting the growth of *B. coli* in dilution of approximately 1 in 200, at which streptococci will grow vigorously, a property which has been found of considerable use in routine bacteriology. This suggests that all these three preparations are closely allied in action, and presumably in composition, to phenol.

To those who regard the predominance of streptococci in the faeces as accountable for chronic ailments such as arthritis, this action on the part of these drugs will hardly commend itself. But before applying such findings to the presumed effect of these drugs on the human subject, it must be asked in what dilution they were present in the intestinal tract when taken in ordinary doses. This cannot be determined unless it is known whether they are absorbed, combined, or destroyed, or unless a method be devised for estimating them in the faeces themselves. The latter, having in view that their composition is unstated, is hardly feasible. But some indication as to their activity, if any, in the colon may perhaps be obtained by comparing the results of the two above series of experiments *in vivo* and *in vitro* respectively. The latter clearly show that in certain dilutions three of these antiseptics exert a selective action on coliform bacilli.

If, in experiments on the human subject, it were shown that although the total numbers of organisms in the stools were unaffected the proportion of streptococci to coliform bacilli was increased, it might be presumed that this change had been brought about by the action of the antiseptic, and therefore that its dilution in the bowel is something in the neighbourhood of 1 in 2,000. That this is probably not so is shown by the following figures, which refer to the same series of experiments as in Table I.

TABLE III.—Average Percentage of Streptococci in Faeces Before and during Administration of "Intestinal Antiseptics."

Antiseptic.	Average Percentage of Streptococci.	
	Before Administration.	After Administration.
Dimol	34	51
Kerol	4	3.9
Izal (1925)	31	36
Izal (1925)	46	37

In only one case, that of dimol, is there an appreciable increase in the number of streptococci in the stools during treatment, and even this is not sufficient, as an unconfirmed observation, to indicate with certainty that the drug is exerting its selective action *in vivo*, although the fact that it possesses this power *in vitro* to a greater extent than either kerol or izal suggests that this may be the case. Kerol and izal do not appear to affect the relative proportions of the two types of organism at all.

If this comparison is justifiable, therefore, it would appear that these drugs do not reach the colon in an active form and sufficient concentration to exert the effect which they are shown to produce on faecal organisms *in vitro*.

Conclusions.

The only conclusion which can with certainty be drawn from these experiments is that the drugs investigated, when given by the mouth, do not appreciably reduce the total number of living aerobic organisms in the faeces. Whether it can therefore be said that they are therapeutically useless is a matter upon which it would be rash to pronounce an opinion. But it may reasonably be submitted, in view of these findings, that specific and detailed evidence as to the alleged action of these drugs should be published in support of the claims which are constantly made for them. It is possible that data exist upon which these claims are founded, obtained by other methods, which traverse the deductions suggested by the experiments here described. If not—if, in fact, these claims are made without due investigation of the results obtainable in the living

subject by the administration of these drugs—then it may reasonably be asked whether any indication exists for their employment.

Summary.

The experimental results obtained may be summarized as follows:

1. Four preparations, of which three are described as intestinal antiseptics, were found to exert no appreciable effect on the total numbers of living aerobic organisms in the faeces when administered by the mouth in adequate doses.

2. Of the same preparations the three referred to above were found to exert on faeces *in vitro* an antiseptic action much greater for coliform bacilli than for streptococci, the concentration of the drugs being considerably higher than that in the intestinal tract which presumably follows their administration by the mouth. The fourth preparation had no evident action whatever in any dilution employed.

This work formed part of a research undertaken for the Gillson Scholarship of the Society of Apothecaries. I am indebted to them, and to Dr. Geoffrey Evans, whose patients were some of the subjects in the investigations.

GASTRIC PAIN.*

BY

CHARLES MILLER, C.B.E., M.D.CAMB.,
F.R.C.P.LOND.,

ASSISTANT PHYSICIAN TO THE ROYAL DEVON AND EXETER HOSPITAL;
CONSULTING PHYSICIAN TO THE LONDON HOSPITAL.

NORMAL digestion should be without sensation except for such feelings as those of satisfied hunger and a renewal of energy. Unpleasant sensations such as discomfort and pain after the ingestion and during the digestion of food are symptoms of the abnormal. The abnormality may be in the patient's consciousness in that he is in such a state of nervous sensitiveness that the ordinary actions of digestion are felt by him and are unpleasant. But even in these cases the general condition of debility affects the digestive apparatus and produces faulty working. Gastric pain is associated in our minds with the patient who complains of indigestion because there is something wrong with the stomach.

There is no more difficult task in medicine than to unravel the tangle of symptoms which drive a dyspeptic to consult us. Of these symptoms discomfort and pain are prominent. The investigation of the symptoms—that is, the taking of the history—is of the greatest value as an aid to diagnosis. It is to surgery, and not to physiology and medicine, that the credit is due for elucidating the disorders of digestion. Physicians at one time were content to treat indigestion with alkalis and, if that failed, with acids; since surgical measures have come to the fore our knowledge of gastric disorders has increased and the methods of investigation have become more numerous and more trustworthy.

The tripod on which a gastric diagnosis rests is: (1) the clinical examination, of which the history is by far the more important part; (2) the test meal; (3) the radiological appearances of an opaque meal. Of these the radiological findings can be the most definite. An ulcer can in some cases be demonstrated and we then have direct evidence. But most of the radiological evidence is indirect, and is concerned with the observations of position, filling, emptying, and peristalsis. The test meal is valuable, but is more variable as the gastric secretions may vary from day to day and are subject to influences from outside.

The clinician, therefore, still has work to do in examining the patient. The physical examination in gastric disorders seldom reveals any gross sign. There may be a tumour, or visible peristalsis, or a dilated stomach with a splash; but usually rigidity of the abdominal muscles is the only objective sign. At the same time it must be remembered that a full examination must be made, which includes

* A lecture delivered before the Exeter Branch of the British Medical Association, January 8th, 1926.

the lungs, the nervous system, the urine, and, last but not least, the rectum.

It is well to let the patient say all that he will about his pain after giving him a start. When he has finished his spontaneous account, the examiner can arrange it and amplify it from the answers to leading questions.

Pain must be the subject of many questions. First, its situation is important. Among the organic or surgical dyspepsias left-sided pain suggests gall-bladder trouble or gastric ulcer, and right-sided pain duodenal ulcer. Epigastric pain is a symptom of any gastric disorder.

The next point is severity. Different patients estimate pain in different ways. The robust man who has never been ailing regards any abdominal pain as severe, while a woman, who is used to abdominal pain, will look upon it as a nuisance that will pass away if endured patiently. So, in estimating severity, we must form our opinion of the patient while we listen to the description. A few special questions may help us. Did it make you feel sick? Did it make you sick? Did it make you sweat? Did you faint or feel faint? What are you willing to go through to avoid a recurrence?

Next comes the relation of pain to food. It is well to draw up a time-table of meal times, filling in the usual time of the onset of pain, and to ask also if the pain occurs at night and wakes the patient with any regularity. It is necessary to distinguish the difficulty in getting to sleep, which may be due to flatulence or worry, from the waking up at 2 a.m. on account of pain. It can safely be claimed that freedom from pain between what the patient calls "attacks" is the most important symptom in a gastric or duodenal ulcer, and to a smaller extent of other organic dyspepsias of non-malignant origin.

The patient complains of attacks of indigestion and pain which recur. During the intervals he is fit and has a good appetite. The attacks tend to become more frequent and severe and the intervals shorter and less comfortable. At this stage he stops buying soda-mints and other remedies, and consults his doctor. This condition of periodicity in dyspeptic attacks is the most definite single point in favour of a non-malignant organic lesion. Any patient who gives such an account of his symptoms should go through a complete investigation by test meal and opaque meal. Regularity of pain is a striking feature in some cases. It is greatest in cases of duodenal ulcer, and less in gastric ulcer. It is more changing in its times in dyspepsia due to gall stones, and in its severity in that due to chronic appendicitis. How relief is obtained is important. If vomiting occurs, does it relieve? Has medicine given relief? Does lying down make any difference? Do all measures have apparently no effect?

Before trying to explain the cause and significance of gastric pain, it will be advisable to mention other painful conditions occurring in the dyspeptic.

There is in some cases hyperaesthesia of the skin of which the patient may be conscious. He may say that the touch of the bedclothes gives him a peculiar sensation. But more often this hyperaesthesia is found only on testing the sensibility of the skin. It is a peculiarity of sensation due to the increased sensibility of the spinal segment which innervates both the disordered viscus and the area of skin.

Tenderness is a more definite phenomenon. It is entirely objective and is produced by pressure. The best way to discover tenderness is to palpate the abdomen with varying degrees of pressure and to ask the patient to say at once if the examination of any spot is painful. Tenderness is not of simple origin. It may be due to the irritation of nerve endings in the subperitoneal connective tissue by the action of some irritant process such as inflammation, or by a mechanical factor such as spasm of stomach or intestine, or pressure may be painful when the abdominal muscles or segments of them are in a state of tonic contraction. This rigidity can be regarded as protective, the contracted muscle fibres shielding the troubled organs below. It is obvious that these two causes of tenderness may be present at the same time. But rigidity, and tenderness due to muscular contraction, are the commonest objective signs in the various forms of dyspepsia, the upper segments of the recti muscles being most frequently affected, especially the right. Pain and tenderness may

be due to the irritation of nerve endings when an organic lesion such as ulcer invades neighbouring tissues. But having mentioned these forms of sensation that can be called painful we are still left with the pain of which the patient originally complains.

This pain is the true visceral pain, and may be present in organic and functional disorders of digestion. It is not due to a sore mucous membrane. The sensations of pain, heat, and cold are not referred to consciousness as such from the nerve endings in the mucous membrane of the gastro-intestinal tract, except in a very minor degree. These forms of sensation are only found fully developed in surfaces covered with a stratified epithelium. Columnar and cubical epithelium are without, or almost without, these forms of sensation. This statement can be illustrated by stimulating the mucous membrane in a case of colostomy. Touch, pin-prick, heat, and cold do not impose themselves on the consciousness of the patient. But if it be dragged on gently with forceps the patient will at once tell you that he feels something, and if you drag hard enough he will complain of pain.

Further, in many cases of organic dyspepsia, such as duodenal and gastric ulcer, a notable feature is its periodicity. The ulcer at certain times is not associated with pain. It is reasonable, then, to regard the mucous membrane as not being the sensitive tissue, but to look elsewhere.

It is beyond dispute that when pain is felt nerve units are abnormal or are abnormally stimulated. In gastric visceral pain we have to seek for something which is capable of producing pain and is behaving abnormally. Of the three coats of the stomach the mucous coat is ruled out, and the peritoneal coat is more concerned with tenderness, an ordinary somatic painful sensation which is elicited by palpation. There is left the muscular coat. We have seen that traction on the intestine in colostomy will evoke a painful sensation if sufficiently strong. The bulk of the evidence obtained by radiological examination is the record of the position and the observed movements in stomach and duodenum. It has been shown radiologically that hunger pains coincide with movements of the stomach. We know that stretching and over-contraction of skeletal muscle are painful, and the same is true for smooth muscle.

If we attempt to correlate the pain of dyspepsia with the actions of the muscular coat we get a very reasonable explanation. Take, for example, a case of chronic ulcer of the lesser curvature of the stomach; the usual time for pain is twenty to thirty minutes after food; its arrival in the stomach produces functional activity with a secretion of acid juice. The muscle fibres or the nerve endings of the muscle fibres are stimulated by the contents of the stomach, and a painful contraction takes place. The contraction may be painful either because it is a cramp or because there is a pull on subperitoneal nerves by contracting muscle in the base or edge of the ulcer. When an ulcer is present in the pre-pyloric region the pain will occur later after food, usually one to one and a half hours.

In duodenal ulcer the pain is so late after food that it is dated as being before food; it is relieved by the intake of food, and can rightly be called hunger pain. It is usual for there to be an excessive secretion of acid juice in duodenal ulcer. Hunger pain is a duodenal symptom, not necessarily of ulcer. An explanation of the pain would be that the acid juice in the duodenum causes the pyloric sphincter to contract painfully. It is not an entirely satisfactory explanation, but the hypertonic contraction of the sphincter can be regarded as one cause of pain in duodenal ulcer. This type of pain is a symptom of duodenal trouble, usually associated with hyperchlorhydria. Its repetition after free intervals is the point in favour of duodenal ulcer, especially if haemorrhage has been noticed.

It is obvious that we must seek further to discover why the muscular coat should behave so as to produce pain. Possibly the presence of acid in the stomach is the exciting cause of the abnormal and excessive muscular contraction in gastric and duodenal ulcer. When food is taken into the stomach the resting juice is diluted so that the strength of the acid is lowered. Next the presence of food stimulates a flow of acid juice, and both the amount and the strength of the acid are increased. At the same time the digestive

movements of the stomach have started on their course. This would explain the interval between eating and the onset of pain in gastric ulcers.

In duodenal ulcer the percentage of acid in the gastric juice is nearly always high. The pyloric sphincter relaxes in the presence of acid on its proximal side, and contracts if acid remains unneutralized on its distal side. If the strength of the acid is excessive the contraction of the sphincter is overdone and prolonged. The results of gastro-jejunostomy are said to be the most satisfactory in cases of duodenal ulcer. Perhaps this is because the operation allows a more free regurgitation of alkaline juice into the stomach, and provides an exit that is not guarded by a sphincter.

So that in gastric and duodenal ulcers the explanation of pain and its time-table is the behaviour of the smooth muscle under the influence of acid. In one case the acid stimulates the base of the ulcer, and in the other a highly acid juice produces a cramp of the sphincter.

These symptoms are such as are described by the patient as being characteristic of his trouble in its early days. By the time he presents himself for examination the symptoms are usually more confused, and, during the worst periods, the pain is constant and is bad at all times, soon and late after food. It is necessary, then, to ask the patient to go back and describe the symptoms of the earlier days.

If the ulcer causes a deforming scar, thereby producing either hour-glass stomach or pyloric obstruction, pain will be produced by the stretching of the stomach wall and will only be relieved by vomiting, lavage, or emptying the stomach naturally. A change, therefore, in the character of the pain and other symptoms must be looked for and taken into account. When the history reveals a change of this kind in a case of long duration, the evidence is very strong indeed and a definite diagnosis can be made with great accuracy.

Alteration in the character of the pain will also occur when the base of an ulcer becomes adherent to neighbouring structures, such as pancreas, gall bladder, liver, and crus of the diaphragm. When an ulcer of the lesser curvature becomes adherent to the pancreas, constant pain through to the back will be felt. If the crus of the diaphragm is invaded the pain will be in the shoulder. The same pain will be felt in inflammation of the gall bladder as soon as the diaphragm is affected, though the more constant pain in gall-bladder trouble is through to the scapula.

But these pains are additional and are either referred or due to the implication of subperitoneal nerve endings. The vast majority of dyspeptics, however, have nothing so simple as an ulcer. A very large number complain of pain as soon as food enters the stomach. This may be a temporary affliction or more lasting. It is found in patients who have a tired-out or ill used stomach. At its worst the pain does not go until the patient has vomited. In character the pain is more often a dull aching, and not the violent cramp-like pain such as occurs with duodenal ulcer. It can be regarded as a stretching of atonic muscle fibres. In such patients there is atony of the circular and longitudinal fibres, due either to the general weakly condition of the patient or to some recent misuse of the stomach. The presence of food stretches the muscles and produces discomfort or pain. In the worst cases the strong oblique muscle fibres are also affected and then the symptoms are more lasting. In such cases there is a general dropping of the stomach.

In many of these cases there is a low acidity of the gastric juice. There may also be slow emptying of the stomach. These people may truly be said to have weak digestions. But in some, in which enteroptosis can be demonstrated, there is an increased acidity, and there may be rapid emptying. Here the symptoms may suggest duodenal ulcer, but the absence of the intervals of good digestive health, and the immediate improvement on putting the patient to bed, and other minor points will help to differentiate. It is not necessary for the enteroptotic patient to have indigestion. Many eupeptics have a low-placed stomach. But if some cause of indigestion occurs the presence of ptosis is against the patient's chances of satisfactory relief.

The majority of dyspeptics who seek relief belong to the class of atonics. Very often they are feeble in other ways, and their poor nutrition enhances their general as well as their gastric debility. The surgeons call the condition "medical dyspepsia." They are quite right to avoid operations on such subjects, for they are likely to do them more harm than good. But it is rather sad that the physicians should be left to deal with the most thankless and intractable kind of case. It is still more sad when the physician is called in to make the best of a patient who has had a series of operations, including gastro-jejunostomy, appendicectomy, freeing adhesions, etc. However, a good deal can be done for these atonic patients by putting them in bed with the foot of the bed raised, by giving small feeds frequently, by fitting an abdominal belt, and by massage.

Cancer of the stomach may be productive of pain of the visceral type, but pain must not be regarded as a necessary symptom of cancer. If the cancer cells infiltrate the wall of the stomach, making it stiff and rigid as in the leather-bottle stomach, the capacity of the stomach is incapable of adapting itself to the presence of food. The entry of food may put the wall of the stomach on the stretch and produce instant pain. Or a carcinomatous ulcer may be associated with pain in the same fashion as a non-malignant ulcer by infiltrating neighbouring tissues. But many cases of cancer are painless. Possibly the absence of acidity is responsible for the absence of pain. But the majority of patients who have pain immediately after food have a tired-out or ill used stomach which is in a condition of atony.

Substernal pain, or "pain in the chest"—a symptom of indigestion commonly found in constipated young women and in sufferers from flatulence—is concerned with the cardiac sphincter. Substernal pain may be due to dilatation of the oesophagus because the cardiac sphincter will not relax to allow food to pass into the stomach. In the flatulent, pain is produced by the pressure on the cardiac sphincter until it opens. When the cardiac sphincter opens and the gastric tension is lowered, relief of the pain follows at once. Here again the wrong behaviour of muscle can be blamed for the pain.

In all the cases described it would seem that the visceral pain of indigestion is to be attributed to the condition and the behaviour of the muscular wall of the stomach. If, then, we wish to explain to ourselves the meaning of digestive pain we must express our explanation in terms of muscle. In the disorders of digestion there is infinite variety. A few examples only have been taken to show the significance of the predominant symptom—pain.

In the opinion of the patient pain is of the greatest importance, and if we can understand how the pain is produced we are in a better position to treat it and to prevent a recurrence. We can arrive best at this understanding if we take into consideration the state and behaviour of the smooth muscle of the stomach.

NEPHRECTOMY IN INFANCY.

BY

A. CLIFFORD MORSON, O.B.E., F.R.C.S.,

SURGEON TO ST. PETER'S HOSPITAL FOR URINARY DISEASES; SURGEON TO OUT-PATIENTS, RAMPTON GENERAL HOSPITAL.

ALTHOUGH the removal of a kidney during the first twelve months of life is seldom indicated, nephrectomy may be a life-saving measure. Renal sarcoma in the very young is well known and may produce a tumour of considerable size which is often bilateral. Urinary symptoms are generally absent and attention is first drawn to the lesion by the presence of an abdominal swelling. The general health remains good until pressure of the growth causes obstruction either to the ureter or the adjacent bowel.

Opinions differ as to the origin of these tumours, some holding the view that they are extrinsic to the kidney, while others claim that they are entirely renal. If the latter view is correct, it is strange that haematuria, the common manifestation of all other neoplasms of the kidney, should never be observed, more especially as carcinomatous

elements have been described. This so-called congenital sarcoma is best explained by Wilms's hypothesis, which maintains that it contains three parts—a carcinomatous, a sarcomatous, and a myomatous. All these elements can sometimes be found in the same growth if sections are taken from various portions.

Nephrectomy has been practised for many years with unsatisfactory results, the mortality rate being at least 50 per cent. In those that survive the shock of the operation recurrence is rapid, but from time to time an exception is met with in which clinical evidence is forthcoming that surgery has produced an apparent cure. So long, however, as diagnosis is delayed until pressure symptoms arise, there is more hope for the prolongation of life in the exposure of these tumours to irradiation than in submission to the surgeon's knife.

Experience has shown that if the kidney fails to develop normally during foetal life it is prone to become diseased. All kinds of operations have been devised to restore the kidney to its normal function. Their multiplicity proves that none produce the desired result, and when they are practised nephrectomy is merely delayed. Within the first decade of life hydronephrosis of congenital origin, uncomplicated by infection, causes vague abdominal symptoms which can only be diagnosed accurately by the aid of pyelography. On the other hand, if infection occurs there is little difficulty in determining the site of the lesion. Recently there has come under the care of my colleague, Dr. Adolphe Abrahams, an infant, aged 7 months, suffering from a structural defect of the right kidney.

A child, aged 7 months, healthy and robust-looking, was admitted to hospital on October 10th, 1925, with a history of an attack of diarrhoea and vomiting on October 5th. On October 9th straining and pain during micturition was noticed and the urine was observed to contain a white deposit.

On admission the temperature was 104.2°, pulse 160, respirations 60. The stools were normal. The urine gave an acid reaction, had a smoky appearance and unpleasant odour; specific gravity 1025; microscopically coliform organisms and some pus cells were reported.

The tongue, mouth, and pharynx were clean, and apart from the abdomen being tender and phimosis being present there were no other physical signs.

The alkali treatment of pyelitis was adopted; the temperature and respirations fell steadily, and by October 16th the temperature was normal; urine 30 oz. per diem and alkaline.

On October 29th circumcision was performed. The temperature rose with the onset of bronchitis; a definite deposit of pus appeared in the urine, which had again become acid. The child went off his feeds, and on November 6th the respirations were slow and sighing; temperature 103°, pulse 163.

The urine contained a heavy deposit of pus; no acetone and no diacetic acid present. On November 7th a tender tumour the size of a hen's egg was palpated in the right loin, the bladder was distended, and incontinence with overflow was present. Ten ounces of urine were drawn off by catheter and the bladder washed out with boric acid lotion (half strength), much muco-purulent material being present. On November 8th the above procedure was again attempted, but failed owing to the blocking of the catheter with muco-pus.

Operation.

A small incision was made to the right and above the umbilicus. Intra-peritoneal palpation revealed a right kidney enlarged and cystic and a left kidney normal in consistency and size. This incision was then closed and suprapubic cystostomy performed, a malacot tube being left in the bladder.

The condition of the child improved, and on November 18th the right hydronephrotic kidney with 3 inches of distended and coiled double ureters was removed through a curved lumbar incision; the perirenal tissue was drained by a small tube and a fresh malacot catheter inserted into the bladder.

On November 24th this catheter was removed and the bladder washed out suprapubically. An attempt was then made to cysto-

scope the patient through the suprapubic fistula, but owing to the small size of the bladder and its inability to retain fluid the ureteric orifices could not be seen. The wounds healed rapidly, and though another attack of bronchitis supervened the child is now doing well and gaining weight. This patient has been kept under observation since discharge from hospital. His general state of health is excellent and the urine is normal.

The accompanying illustration demonstrates the chief features of the abnormal kidney. It will be noted that the lower ureter is dilated and opens into a large pelvis and that the calyces are almost entirely absent. The upper ureter is also dilated and opens into an accessory pelvis perched on top of the upper pole. There is no communication between the two pelves. At the operation the two ureters were discovered to unite just before entering the bladder.

In the *Transactions of the Royal Society of Medicine* (vol. xiv, No. iv) Jocelyn Swan records a case of double ureter in a man aged 33, where the accessory duct opened into a cyst at the lower pole of the kidney. I believe that this cyst was really a second pelvis.

It is interesting to inquire why, if the ureteric bud on one side divides to form two ureters and two pelves, the mesonephros on the same side, from which the renal cortex is developed, does not likewise split up into two portions. A case has yet to be recorded of a man with three fully developed kidneys.

I am indebted to Dr. G. L. S. Kohnstam for the compilation of the case notes.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

BROMISM: THE SODIUM CHLORIDE TREATMENT.

Two types of eruptions due to the administration of bromides are described: (1) an acneform (bromacne), usually seen on the face, chest, or back; and (2) a granulomatous hyperplastic variety which occurs most often on the extremities.

An occasional peculiarity is the relatively long latent period between the last dose of the drug and the appearance of the symptoms, which once they are established may "persist for a considerable time after it has been discontinued." These points were well illustrated by a case to which I was called by Dr. D. H. Fraser on January 7th.

The patient, a lady aged 65, was suffering from a left-sided incomplete hemiplegia with some aphasia—her fourth stroke since 1914. Both bromide and iodide of potassium had been administered, the latter continuously for some weeks, and up to the moment of our consultation. The last dose of bromide, in the form of bromoglidin (gr. 5), was given on December 22nd. Its administration had not been regular, but not more than 125 grains of bromoglidin had been given during the period of her illness—seven weeks. The eruption consisted of (1) Reddish, raised, grouped acneform papules on the front of the chest. They were larger and much brighter in colour than acne vulgaris. There was no tendency to pustulation, and there were no subjective symptoms. The face was not affected. (2) The more typical raised granulomatous, discoid plaques, varying in size from that of a shilling to half a crown, were present on the backs of the hands, the dorsa of the feet, and sides of the little and big toes. The first of them had been noticed by Dr. Fraser on the forefinger of the left hand on December 23rd—that is, a full week after cessation of the bromide. These lesions were of a dull red colour, and discharge was oozing freely from a number of points on the surface of each. Three such lesions were present on the right hand, two on the left, and a larger number of less typical patches on the feet. The temperature was not raised, there was no pain or irritation, and the associated glands were not notably enlarged. The case seemed to me, without any doubt, to be a classical example of bromide eruption as suspected by Dr. Fraser.

The duration of such cases may be prolonged. In one of my own cases—a chronic alcoholic who had taken bromide after an attack of delirium tremens for some months, and had in consequence developed severe granulomatous lesions on both legs—in spite of many different applications, and the internal administration of arsenic, healing did not take place for five weeks. I was therefore glad to have the opportunity of testing the efficacy of the salt treatment devised on an experimental basis by Wile, Wright, and

¹ MacLeod: *Diseases of the Skin*, 1920, p. 718.

Drawing to illustrate abnormal kidney in an infant of 7 months

Smith,¹ and later perfected by Stevenson.² The first named, relying on the principle of "mass action" of salts in solution, administered intravenous injections of decinormal sodium chloride to three cases of bromism. "Bromides were detected in the urine when none had been present before, and rapid regression of the skin lesions and improvement of the nervous symptoms were noted."

Stevenson found that oral administration of the salt in salol-coated tablets was even more effective in both respects. A reference to his urinary observations, which are very convincing, will show that the excretion of bromide occurred most rapidly from the fourth to the eighth hour after taking the tablets. In our case the salt was put up in doses of 10 grains in gelatin capsules, and 20 grains were given thrice daily after food, from the morning of January 8th to the evening of January 11th. On this date I saw the patient again. No ill effects, not even thirst, were complained of, and all the lesions had completely flattened down and dried up. Only scaly, slightly brownish patches remained to show where the protuberant lesions had appeared. The local application used was dermatol, which consists mainly of bismuth tannate. That this could not have caused the involution is evidenced by the fact that there was a simultaneous and equal improvement of the acneform papules on the chest, which had received no local treatment whatever. We were much interested by the nurse's observation that the patient disliked salt, and never took it with any of her food.

Although I have only this one case to report I am satisfied that Drs. Wile and Stevenson have found a specific for the treatment of bromism, which is comparable in the rapidity of its effects to the action of salvarsan in secondary syphilis. Its administration in iodism (which may conceivably have complicated the case here reported) will probably be found equally valuable. Dr. Stevenson states that nephritis is a contraindication to sodium chloride treatment.

London, W.

HENRY C. SEMON, M.D., M.R.C.P.

OPERATIVE TREATMENT OF CANCER OF THE COLON.

SOME two months ago I had occasion to collect statistics of the cases of cancer of the colon upon which I had operated during the past eight years. After reading Professor Pannett's article in the *BRITISH MEDICAL JOURNAL* of January 2nd (p. 1), it occurred to me that the figures might be of sufficient interest to publish. The number of cases is small, but the results are to some extent encouraging.

The series is made up of twenty-five cases of carcinoma and one of sarcoma. The oldest patient, a case of colostomy, was 84 years of age, while three patients were under 30.

OPERATIONS PERFORMED.

Resection.—Fourteen cases, of whom eight were suffering from acute obstruction at time of operation. Of these fourteen cases there were:

- Two cases of primary resection, both for growths of caecum, with no deaths.
- Three cases of axial anastomosis, after preliminary drainage, with one death.
- Nine cases of resection by Paul's two-stage method, with one death.

Lateral Anastomosis.—Seven cases with no death:

- Caecum to transverse colon ... 3 cases.
- Transverse colon to transverse colon ... 2 "
- Transverse colon to sigmoid ... 1 case.
- Ileo-colostomy plus appendicostomy ... 1 "

Colostomy.—Five cases with no death.

Total.—Twenty-six cases with two deaths.

RESULTS.

Resection.—Two died as a result of operation. Five died of recurrence after periods varying from one to four years. Seven are still alive, one after eight years, the others after fifteen months or less. The patient who has survived eight years is a woman, now aged 67. At the time of operation she was suffering from acute obstruction due to a growth in the sigmoid. She is able to get about the house, but has symptoms which suggest secondary deposits.

Anastomosis.—One died after three years, one after eighteen months, two after six months. Three are still alive, one after

seventeen months, one after fourteen months, and one more recent.

Colostomy.—No attempt was made to trace the cases of colostomy. They all left hospital in fair health.

Deaths.—The first case was an army sergeant, aged 23, operated on after acute obstruction had existed for several days. A sigmoid growth was resected and Paul's tubes tied in. He died three days later. A preliminary drainage would have been wiser. The other case was a stout unhealthy man of 50 suffering from acute obstruction due to a growth in the splenic flexure. Caecostomy was performed by invaginating a rubber tube. Eight days later the growth was resected and axial anastomosis performed. Unfortunately the caecostomy ceased to drain and leakage occurred at the suture line. It would have been better to have fixed the caecum to the skin at the first operation so as to ensure adequate and prolonged drainage. The valvular caecostomy tended to close too quickly.

For growths situated in the distal half of the colon I think Paul's operation is still the operation of choice. Its ease and safety more than counterbalance its drawbacks.

The case of sarcoma of the caecum was that of a man of 30; an appendicular abscess had been drained during the war. Lately he had had attacks of pain and vomiting which were thought to be due to the appendix, which had not been removed. On opening the abdomen the caput caeci was found to be thickened and hard and the mesenteric glands enlarged. The caecum, together with the ascending colon and affected glands, was removed. Histological examination showed the growth to be a sarcoma. The patient was alive and at work six months after the operation.

The value of lateral anastomosis does not seem to be sufficiently appreciated. Colostomy was done only in cases of fixed growth low in the sigmoid. I quote cases illustrating the value of lateral anastomosis.

A frail woman, aged 69, had a growth in the hepatic flexure which caused symptoms of obstruction. I anastomosed the caecum to the transverse colon, and her doctor told me that she lived in comfort for three years, taking to her bed only a fortnight before she died.

Within the course of three months I operated on two old ladies, each 77 years of age, and each having a growth in the middle of the transverse colon. In each I anastomosed the bowel on either side of the growth. They are both alive, active, and free from discomfort, one seventeen months and one fourteen months after operation.

In July, 1921, I operated on a man of 49 suffering from acute obstruction due to a growth in the ascending colon. I relieved the obstruction by appendicostomy. Nineteen days later I divided the ileum, 6 inches from the caecum, and inserted the proximal end into the transverse colon. The growth was irremovable and I left the appendicostomy to drain the excluded bowel. He went home weak and emaciated and I thought he would not live long. Nine months later he turned up looking plump and well. He wanted to be relieved of the mucous discharge from the appendicostomy. He seemed so well that I reopened the abdomen in the hope that removal of the growth might be possible. I found it impossible, but he lived another six months.

I hope these somewhat discursive notes may help to prove that surgery may do much to alleviate, if not to cure, even advanced cases of cancer of the colon.

C. C. HOLMAN, M.B., F.R.C.S.,
Surgeon, Northampton General Hospital.

APPENDIX IN HERNIAL SAC.

A MAN, aged 60, admitted for the radical cure of inguinal hernia to the War Memorial Hospital, Congleton, gave a history of four months' duration. A well defined hernia of about the size of a hen's egg presented at the right external abdominal ring. The hernia could be easily reduced, and evidently contained intestine, from the gurgling sound accompanying reduction. A soft mass which remained behind in the inguinal canal and could not be reduced was taken to be an unusually thick sac or an omental lipoma.

At the operation the inguinal canal was found to contain a fatty lobulated mass rather larger than a duck's egg, and embedded along its lateral border was the appendix, which was firmly adherent to the fatty mass, especially at the tip. Careful examination of the surrounding parts showed that the fatty mass did not arise from the omentum, but was the appendix mesentery in a lipomatous condition. A small portion of the caecum surrounding the base of the appendix could with difficulty be pulled through the internal abdominal ring, and it was just possible to get a purse-string suture in position and invaginate the stump of the appendix after removal. If the caecum could not have been pulled through the internal abdominal ring, thus allowing complete removal of the appendix, it is doubtful if the lipomatous mass could have been returned inside the abdomen.

A CASE OF PERNICIOUS ANAEMIA.

THE extremely low blood count in this case seems to make it worthy of record. Though several cases have been reported with a lower cell count they are comparatively rare.

A woman, aged 57, was admitted on November 21st, 1925, complaining of jaundice and weakness, which had only commenced twelve weeks before. Previously she had been a healthy woman.

The symptoms were: jaundice, which had never been intense, great weakness and lassitude, severe headaches, no appetite, marked thirst, occasional nausea and vomiting, loss of weight, and troublesome constipation. There was no history of hæmorrhage, and no shortness of breath. The menopause occurred when she was 47 years of age. She had had nine children and five or six miscarriages. She was extremely weak, and seemed to be rather wasted. The tongue was clean and smooth, but not glazed. The mouth was edentulous; all mucous membranes were very pale. The skin was lemon-yellow in colour, and there were no petechial hæmorrhages. The pulse was weak, and the blood pressure 70/38. The heart was not enlarged, and there were no bruits. The edge of the liver was just palpable below the costal margin; the spleen could not be felt. The knee-jerks were present, and were not exaggerated. Other reflexes were normal.

After admission her general condition became rapidly worse. She was delirious, and was incontinent of urine and faeces. Blood transfusion, performed as a last resort, was followed by slight improvement, but she soon collapsed, and died a few hours later, four days after admission. A *post-mortem* examination could not be obtained.

The pathological report on the blood was as follows: Red cells 300,000 per c.mm., white cells 25,200 per c.mm., hæmoglobin 8 per cent., colour index 1.2. Differential count: Polymorphs 46, lymphocytes 51, eosinophils 0, mononuclears 2, myeloblasts 1. The film showed many normoblasts, a fair number of megaloblasts, and a few myeloblasts. Anisocytosis and polychromatophilia were marked, poikilocytosis less marked.

The interesting features in this case were: the short history with final acute exacerbation of symptoms and rapid termination, the low red cell and hæmoglobin percentage, and the absence of many of the classical physical signs.

I am indebted to Dr. Cleveland, to whose ward the patient was admitted, for permission to publish this case.

D. B. SUTTON, M.B., M.R.C.S.,
House-Physician, Norfolk and Norwich Hospital.

BILATERAL RENAL ANEURYSM.

OSLER states that renal aneurysm is not very uncommon, but gives no statistics. In *Allbutt's System of Medicine* the same statement is made. The following case was the only example of renal aneurysm found in a series of 112 consecutive *post-mortem* examinations, and hence deserves mention.

A woman, aged 57, was admitted to hospital on November 22nd, 1925, as a case of dementia. There was a history of her having had a stroke in 1918, with subsequent development of slow, thick speech. On August 13th, 1925, she had an apoplectic seizure with convulsions and tremors of right face, arm, and leg. Blood pressure 240/140. The urine showed a light cloud of albumin and some hyaline casts. Both the blood and cerebro-spinal fluid gave a negative Wassermann reaction. Death occurred in five days from pneumonia.

Post-mortem Examination.

The right renal artery was tortuous and presented a firm swelling, the size of a Tangerine orange, at the entrance to the hilum. Three swellings, the size of peas, were present on subdivisions of the artery. On section the main swelling showed a thickened and calcified wall, with a lumen about the normal size of the artery, and occupied by recent blood clot. The smaller aneurysms also showed calcified walls. The left renal artery had tumours in the same position, but on a slightly smaller scale.

Both kidneys were small, with capsules thickened and densely adherent. The surfaces were coarsely granular and exhibited numerous small clear cysts. Section showed atrophy of the cortex with loss of radial markings, pallor of pyramids, increased hilar fat, and prominent open-mouthed vessels. Microscopic examination showed marked increase of well formed fibrous tissue and degeneration of tubules and epithelium; all vessels showed sclerotic changes. Section of the aneurysmal wall showed proliferation of subintimal connective tissue, with calcareous deposits, thinning of media, and loss of elastic tissue fibres in adventitia. Thus it is evident that the aneurysmal dilatation of the renal vessels was a sequel to arterio-sclerotic changes.

Examination of the heart showed marked concentric hypertrophy of the left ventricle, and atheroma of the coronary arteries. The brain showed sclerosis of all arteries, particularly of the basal. Three hæmorrhagic sites were present: the oldest, the size of a walnut, in the right internal capsule; the intermediate, the size of a Spanish nut, in the left internal capsule; and the most recent, the size of a walnut, just anterior to the genu of the left internal capsule.

I am indebted to Dr. G. Hamilton Grills, medical superintendent, for permission to publish this case.

Reports of Societies.

GALL STONES: ETIOLOGY AND DIAGNOSIS.

A MEETING of the Medical Society of London was held on February 22nd, with Sir HOLBURN WARING in the chair, to discuss the etiology and diagnosis of gall stones. The three openers dealt with the subject from the medical, surgical, and radiological aspects respectively.

Sir HUMPHRY ROLLESTON began by remarking that it had been epigrammatically said that gall stones were most often reported in "females over forty, fat, flatulent, and fertile." The reference to fertility was on account of the tendency for pregnancy to produce an increased content of cholesterol in the blood. He did not propose to discuss at any length the two theories of etiology—the infective theory on the one hand, and the metabolic or biochemical theory on the other. Roughly, it might be said that pure cholesterol stones, which were single, and which seldom gave rise to any symptoms except when they happened to be impacted in the cystic duct, were formed metabolically, while the common mixed calculi seemed to depend to a considerable extent—perhaps entirely—upon an inflammatory process. In passing, he mentioned the effect of famine conditions upon gall-stone incidence. Statistics from a hospital in Leningrad showed that in 1914 the incidence of gall stones was 0.47 per cent., and in 1919, as a result, no doubt, of deprivation of food among the population, it had fallen to below 0.1 per cent. The same thing had been observed with regard to other metabolic diseases, such as diabetes. Sir Humphry Rolleston passed on to speak of diagnosis from three points of view: clinical observation, radiological methods, and laboratory methods. Calculi in the gall bladder very seldom set up purely mechanical effects, but the physician had to deal with masked or inaugural symptoms, reflex effects, which only with great difficulty were to be distinguished from dyspepsias due to other causes. It had always been a matter of surprise to him that so few people traced the existence of gall stones to an infection derived from the colon. An American observer, speaking of 400 gall-stone cases, in 170 of which he incriminated the alimentary canal, said that of these 170 no fewer than 100 were to be referred to infection from the colon. With regard to the various migrations of calculi from the gall bladder, giving rise to symptoms more definitely related to irritation of the alimentary canal, the speaker referred to those curious manifestations of biliary colic which might imitate angina pectoris. In some of these cases it was possible that there was a definite cardiac lesion, perhaps secondary to infection absorbed from the gall bladder, which rendered the myocardium more susceptible to referred pain than it otherwise would be. With regard to radiological diagnosis, x-ray examinations were becoming of increasing value in gall stones and gall-bladder disease. The ordinary direct method of showing the gall stone on the plate, which gave positive results in about 50 per cent. of cases, had been progressively improved, and by the use of certain bromine and iodine compounds some still more interesting results had been obtained. The intravenous injection of these drugs, however, had given rise to such severe reactions that he thought it had been abandoned in preference for a method whereby the salts were given orally in the form of a pill. Laboratory tests, he thought, were less helpful in gall-bladder diseases than in many other conditions. The idea that a high cholesterol content of the blood pointed to the presence of gall stones had been recently contested. However this might be, most clinical observers would agree that in a doubtful case if there was a definite increase in the amount of cholesterol this fact would incline them in favour of gall stones as against, perhaps, duodenal or gastric ulcer. He did not think test meals helped very much. It had been stated that the vast majority of cases of gall stones showed a diminished content of hydrochloric acid, but this was not at all a unanimous view.

Mr. R. P. ROWLANDS, speaking as a surgeon who had had many opportunities of confirming or contradicting the diagnosis of gall stones, said that at present the chief

reliance must still be placed on a very careful and painstaking study of the clinical symptoms and ordinary physical signs. Although some of the x-ray and biochemical tests were useful, they did not approach in value the simpler clinical method. Accuracy, however, was to be attained only by tapping every source of information, so that there was much to be said for a complete routine examination in all except urgent cases. The site of the pain and tenderness generally distinguished gall-bladder trouble from appendicitis, though all surgeons were familiar with the difficulty of the misplaced appendix, which might lie quite close to the gall bladder, and then an exploration was the only means of settling the diagnosis. The symptoms of gall-bladder trouble were more vague and capricious than those of duodenal ulcer. The x-ray shadow was often of great value, though he could not subscribe to Sir Humphry Rolleston's estimate. The x rays had not shown the gall stones in anything like 50 per cent. of the cases in which he had removed these concretions. The x rays were useful in distinguishing gall stones from cancer of the stomach, in which, on careful and repeated examination, a characteristic defective filling should be proved. In impaction of the cystic duct severe colic, not associated with jaundice, was the symptom. Obstruction of the cystic duct was not invariably due to the calculus; it might be due to kinking or other causes. In the common bile duct the impactions might not always be stone; he had known a blood clot here to lead to a mistake in diagnosis, also a daughter cyst from a hydatid on the liver. An error in diagnosis had often been caused by the pressure of a growth upon the common bile duct. The diagnosis of gall stones was far from easy, and if the untold misery and pain which they caused were to be relieved exploration of the abdomen was often necessary to establish the diagnosis and bring about the cure. Having opened the abdomen, the surgeon had to confirm, complete, or disprove the diagnosis of gall stones or of cholecystitis, which was just as important. It had to be remembered that although gall stones might be present they might not be the sole cause of the symptoms; hence, as a rule, a careful examination of the whole biliary apparatus was indicated, otherwise stones in the common bile duct were apt to be overlooked. The history of jaundice or its absence was not reliable.

Dr. ROBERT KNOX showed a large number of radiographs in which gall stones were more or less visible. The pictures illustrated the wide area within which such stones might occur, and their striking differences in size, shape, and density. A very striking series of radiographs had been sent to him specially for that meeting by Dr. James Stewart of New York; these illustrated the value of the oral method with tetra-iodo-phenolphthalein for showing up the stones. Dr. Knox said that gall stones were first detected by x rays by Carl Beck, in New York, in 1899. Beck discovered two large stones in the gall bladder, two smaller ones in the liver, and one in the cystic duct. The great work done on the subject in this country by Thurstan Holland began in 1905. The conservative estimate of the Mayo Clinic at present was that gall stones could be demonstrated by x rays in 38 per cent. of the cases in which they occurred; on the other hand, two other American workers, Leonard and George, claimed 80 or 90 per cent., this including, however, not only direct demonstration but indirect—that is, deformities due to pressure. Dr. Knox's own experience pointed to a figure nearer that of the Mayo Clinic, or certainly not higher than 50 per cent. He believed, however, that when the use of tetra-iodo-phenolphthalein became general, with a safe and perfected technique, very few cases of disease of the gall bladder would escape detection. The intravenous injection of these dye substances had proved dangerous in some cases, and an oral method, in which a capsule was administered, had been substituted, but in his own work this had not proved very satisfactory because of the difficulty of getting the capsule to break up and absorb in the small intestine.

Mr. PATRICKSON ROSS said that in the surgical unit at St. Bartholomew's the oral administration of the salts mentioned had been tried and had not proved satisfactory. After the work of Wilkie and Illingworth had been published (JOURNAL, December 5th, 1925, p. 1046) it was determined to make intravenous injections of sodium tetra-iodo-

phenolphthalein. The first case so dealt with turned out a complete success; the definite shadow of the gall bladder was shown, and there was no reaction. The method had been used in five cases, but in the last two there were alarming reactions, and he made up his mind not to attempt the method in any others. The patient felt extremely faint, there was great pallor, sweating, a fall of blood pressure, and a drop of the pulse rate to below 50. The patient became quite unconscious, and it was three hours before he was restored to normal. It had been suggested that these effects might be due to some alteration in the solution, in which apparently the salt was not stable. There was no doubt whatever that the solution became intensely toxic on keeping, even in ampoules. If the experiment was repeated care would be taken to ensure the freshness of the solution and the absence of toxic properties. With regard to cholesterol in the blood, there was one point which might be of assistance in diagnosis. Sometimes it was difficult to determine whether jaundice was due to a stone in the common bile duct or to a growth at the head of the pancreas. He understood from Dr. Mackenzie Wallis that the blood cholesterol was always lowered in the case of new growths. If, therefore, there was a tendency in cases of gall stones for the blood cholesterol to be high, and if it was proved in a long series of cases that malignant disease was associated with a low blood cholesterol, the point might be of considerable value.

Sir CHRIS ENGLISH referred to the sedentary life as a predisposing cause of gall-stone formation. Sir Humphry Rolleston elsewhere had described it as a disease of literary men and of persons confined in gaols. In the speaker's view gall stones were extremely common. Many years ago he analysed the post-mortem records at his hospital for the previous ten years, and out of 4,500 examinations found gall stones noted in 242. He believed that in any average company of, say, fifty individuals two might be expected to have gall stones, though the probability was that in neither case would they present any kind of symptoms. Diagnosis was mainly a matter of hard clinical work; most of the accessory methods at present helped very little.

Dr. F. PARKES WEBER spoke with regard to tests for hepatic efficiency in the diagnosis of cirrhosis of the liver, and the importance of such tests in order to avoid mistaking cirrhosis of the liver for cholelithiasis, which might have disastrous consequences. He knew of cases in which patients who had almost certainly subacute hepatic degeneration had been operated upon on the supposition that they were suffering from cholelithiasis, with the result that the anaesthetic had produced death following from a subacute or acute hepatic atrophy. He insisted strongly that the test for hepatic efficiency ought to be used by surgeons in order to avoid the danger of operating when there was a condition of subacute atrophy of the liver or parenchymatous degeneration.

Dr. LENOX WAINWRIGHT mentioned that the salts used in the method of cholecystography described were very unstable in light, and even in ampoules would probably alter in character.

Sir WILLIAM WILLCOX thought that the chemical analysis of gall stones had not received adequate attention. About two years ago he had a case which showed the gall stones extraordinarily clearly—so clearly that it seemed difficult to believe that what was seen was an ordinary x-ray photograph. The patient was operated on, and the gall stones were found on analysis to contain quite an appreciable amount of copper. He believed that in those cases in which gall stones showed up very clearly indeed an analysis would reveal definite traces of copper. With regard to the intravenous injection of tetra-iodo-phenolphthalein, his attention recently had been called to several cases of severe collapse as a result of this injection. Personally he would advise against intravenous injection for the diagnosis of gall stones; it was undoubtedly a severe operation, though possibly improved technique would in the course of time modify the dangers. At present it was not worth while risking the patient's life in this manner. He had been glad to hear Mr. Rowlands emphasize the importance of clinical examination. One useful observation in cases subject to attacks of pain and colic was obtained by taking

the temperature every four hours. If the gall bladder was involved in such cases a rise of temperature to 100° or thereabouts was nearly always found. The four-hourly record of temperature in attacks of colic was of real value in diagnosis. He did not think the test-meal examination in gall-bladder cases was of much assistance.

Dr. KNYVETT GORDON was of opinion that the *B. coli* had a good deal to do with the etiology, but an abnormal strain and not the ordinary *B. coli* was concerned. Whenever the *B. coli* produced symptoms it was not the ordinary organism. When the *B. coli* was found in the stools it might be subjected to certain tests, including its behaviour on preliminary incubation with normal human serum. One often found in the faeces the abnormal *B. coli*; the normal might be disregarded. Dr. RALPH KNOTT described an analysis, undertaken at Guy's Hospital, of the duodenal contents in a large number of cases of proved or suspected gall-bladder disease. Cholesterol crystals, he thought, had been found in about half the cases. Several of the cases had pathogenic coliform organisms, and in two or three cases typhoid bacilli had been isolated.

Mr. J. B. HUME spoke of the condition known as "strawberry gall bladder," and mentioned gall bladders which were packed entirely with small cholesterol stones. A nucleus became detached in the lumen of the gall bladder, upon which salts were deposited, thus giving rise to mixed or pure cholesterol stones, but such stones must surely be considered as of metabolic rather than infective origin.

Sir HOLBURN WARING asked whether Sir Humphry Rolleston had ever come across a case in which he was able to make out the gall bladder and to feel the gall stones on manipulation crunch together like keys in a bag; he had had experience of that on one occasion. With regard to what Sir William Willcox had said about the four-hourly temperatures, this apparently did not always apply. He had a case recently, an elderly man, with a swelling in the region of the gall bladder, but with no stone demonstrable by x rays. He was in doubt as to whether there was a gall stone in the common bile duct or a carcinoma in connexion with the head of the pancreas. Here the four-hourly temperatures showed nothing abnormal. He operated and found the gall bladder enlarged, but with no evidence of stone, but he discovered a little hard mass at the opening of the common bile duct into the duodenum which proved to be an impacted stone.

Sir HUMPHRY ROLLESTON said that he had never come across the condition of "keys in a bag," such as the President had described, and he would have thought it unlikely to occur, but, of course, he accepted the observation. With regard to increased diastase in the urine which had been mentioned, he would have expected that as pancreatic disease was such a common accompaniment of gall-stone disease, the presence of diastase would not be really of very great use. Mr. ROWLANDS, in his reply, mentioned one or two other sources of error at operations; and Dr. KNOX spoke in answer to what had been said about the dangers of administering the dye solutions. The oral method was not free from danger, but very few unfortunate results had so far been recorded.

X-RAY DIAGNOSIS OF TRIPLET PREGNANCIES.

At a meeting of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine on February 4th, the President, Mr. T. G. STEVENS, in the chair, Dr. G. F. ABERCROMBIE reported a case in which triplets had been diagnosed by x rays.

Dr. Abercrombie described the clinical details of the case as follows.

In a woman, pregnant about twenty-eight weeks, it was doubtful whether the child was living; two weeks later the uterus had almost reached the xiphisternum, and twins were suspected. An x-ray examination showed that there were certainly two heads, if not three—one in the left hypochondrium, and one in each iliac fossa. There was no other evidence of multiple pregnancy. Premature labour supervened, and one hour after the membranes had ruptured a male foetus, weighing 3 lb. 3 oz., was born. No placenta followed, and the second bag of membranes was artificially ruptured, during the remainder of that day and the whole of the next, no progress was made. On the following day the uterus was stimulated by castor oil and quinine; labour recommenced at once, and a second child, weighing 3½ lb., was born

by the breech, after a leg had been brought down. The third child lay transversely, and was extracted as a breech case; it weighed 2 lb., and, like the previous two, was a male. All three children were delivered alive, and a single large placenta, with three amniotic cavities and three umbilical cords, was removed manually. The smallest child died on the second day, the next on the fifteenth; the largest regained its birth weight at the end of the fourth week and was doing well.

Dr. Abercrombie showed an x-ray photograph, which clearly revealed two heads, and the third less distinctly.

Mr. W. GILLIATT gave details about the same case, and added that the mother's pelvis was somewhat contracted, the external measurements being 9½ in., 10 in., and 7½ in. The promontory of the sacrum was easily within reach from the vagina at a distance of 4 in. The puerperium was comparatively uneventful, but four hypodermic injections of sensitized streptococcus vaccine were given prophylactically. The case was an admirable example of the great value of x rays in ante-natal work. At a comparatively early stage of pregnancy, when all other diagnostic methods gave no assistance, x rays provided accurate information of the position and of the number of foetuses present. As far as Mr. Gilliatt had been able to ascertain from a search through the literature, triplets had been demonstrated by x-ray examinations on three previous occasions. He added that he had had a similar case of triplets so diagnosed in March, 1925; the three children were delivered by Caesarean section, and all were males. During the previous month he had had a case of hydramnios in which it was impossible to distinguish the foetal parts. An x-ray examination revealed one child presenting by the head, and in three photographs no vault could be seen in the skull. A diagnosis of an anencephalic foetus was made, which proved to be correct.

Late Hydronephrosis.

Mr. HERBERT PATERSON read a short paper on hydronephrosis occurring eight years after ligation of the ureter, and showed a specimen. The clinical details were as follows.

In 1913 he had performed total hysterectomy for a large uterine fibromyoma in a woman aged 43. Part of the tumour had burrowed between the layers of the right broad ligament, and had apparently grown round and underneath the right ureter. Since dissection of the ureter would have been very difficult, if not impossible, the wisest plan appeared to be to divide it and ligature it above and below the fibromyoma. The patient remained quite well for three weeks, when she had a rigor and a temperature of 103° F., followed by several attacks of vomiting, with severe abdominal pain. Four weeks after the operation an elastic swelling was discovered in Douglas's pouch; it was opened through the roof of the vagina, and a large amount of serous alkaline fluid was evacuated, apparently due to a serous perimetritis. The patient made a speedy convalescence, and remained quite well, except for occasional incontinence of urine. Eight years later she began to suffer from pain after food, with a sensation of fullness; the pain was relieved by lying down. A swelling was found in the right lumbar region, and with a cystoscope urine was seen coming from the left ureter. The abdomen was reopened, and it was found that the right kidney had become a large, thin-walled sac, filled with fluid. The right ureter was dilated to the size of the small intestine and could be traced down to the brim of the pelvis. The swelling was removed, together with the ureter; the patient made an uninterrupted recovery and had remained well for four and a half years.

The point of interest in the specimen was that the kidney continued to secrete though the ureter had been ligatured, contrary to statements in the textbooks. A possible explanation was that when the ureter was tied close to the kidney, the back pressure in the kidney caused immediate cessation of secretion; when, however, the ureter was tied nearer to the bladder the pressure of the secreted urine was sufficiently great to distend the thin-walled ureter, which dilated so slowly that the back pressure in the kidney was not high enough to cause total suppression of urine. The slow secretion of the kidney continued consequently, but gradually the renal substance atrophied and was absorbed. The lesson would seem to be that the ureter should have been tied close to the renal pelvis.

Dr. HERBERT SPENCER said he had cut the ureter in performing hysterectomy for large myomata on two occasions. In one case he had brought out the ureter through the flank and drained and subsequently removed the kidney. He thought it likely that a careful examination of cases in

which the ureter had been tied would show that hydronephrosis developed more frequently than was thought by some operators. In the second case he had implanted the upper end of the cut ureter into the lower end by the following method. A long strong black thread transfixed the upper cut end, and one of the free ends of the thread was threaded into an eyed probe and the two ends of the thread tied. The probe was then passed through the lower cut end of the ureter into the bladder. The lower end of the probe was guided by the fingers feeling through the bladder wall into the jaws of forceps introduced through the urethra. The probe and thread were then withdrawn through the urethra. By making traction on the thread the upper end of the ureter was invaginated into the lower and the outer walls were stitched in position with fine silk. The thread was then cut and removed. Both the patients remained well after many years.

Pulmonary Tuberculosis complicated by Pregnancy.

Professor LOUISE McILROY, in a paper on pulmonary tuberculosis complicated by pregnancy, laid stress on the fact that British obstetricians had paid little attention to the subject of tuberculosis complicated by pregnancy; as a consequence, there was little co-ordination between the maternity hospitals and the sanatoriums in the treatment of ante-natal and post-natal cases. Much could be done for patients of the working classes by the provision of special sanatoriums for maternity cases or beds in an obstetric institution. No interruption of sanatorium treatment should be permitted during labour or the puerperium. In the ante-natal clinics the type of disease most frequently met with was that where a tuberculous lesion had started before the onset of pregnancy. Although the patient might appear to be improved because of the pregnancy, this improvement was as a rule only fictitious. Reversion to the original condition usually followed delivery, and, in some instances, the disease might progress, with a fatal ending. Pregnancy was a disaster in the case of a patient with a tuberculous lesion. In the ante-natal clinic symptoms of tuberculosis might easily be overlooked until the lesion was advanced. Induction of therapeutic abortion was the problem of the obstetricians, and opinions were very much divided as to its merits. It should never be a substitute for efficient treatment, and it was very doubtful whether its employment was of much benefit to the patient. The treatment of the disease should be the primary consideration, and the pregnancy be allowed to take care of itself unless the mother's life was in imminent danger from the presence of the ovum in the uterus. Careful consideration must be given to each patient, and the facilities available for satisfactory treatment. If abortion was decided upon it should be induced not later than the twentieth week. Pregnancy should be avoided when any active tuberculous lesion was present in the lungs, and only permitted when the lesion had been healed for a period of two years at least. Patients should be placed under the care of a chest specialist after delivery. The infants of tuberculous mothers were very frequently born in a healthy condition. Breast-feeding should not be employed if there was any active lesion, as there was a danger of exhaustion and infection of the child by direct contact. Professor McIlroy showed charts with the records of cases of tuberculosis and pregnancy and their histories after the confinement.

Dr. HERBERT SPENCER was surprised to hear it suggested that it was only recently that British obstetricians were objecting to the induction of labour. More than thirty-six years ago, in the Obstetrical Society of London, the question "Should pregnancy be terminated prematurely in cases of phthisis?" was raised by the late Dr. William Duncan. A very full discussion followed, in which the operation was condemned (for reasons which remained equally valid to-day) by all the leading obstetricians of the time—Matthews Duncan, Priestley, Playfair, Herman, Cullingworth, Champneys, A. Routh, etc. (*Transactions of the Obstetrical Society of London, 1890, vol. xxxii, p. 7*). The fact that an obstetrician was asked by a general physician to induce abortion was no justification for his doing it. The speaker had been asked to do it

and had always refused, as did Dr. Cullingworth in the case which gave rise to the discussion. It was certain that in some cases the patient's condition improved during pregnancy and that the children were usually strong and healthy; in some cases the condition became worse. No one could say with any certainty that abortion would improve matters, or be justified in deciding that because the mother might be killed by the disease the child should be killed by the doctor. The speaker would regard it as regrettable if there were expressed by that Section a general approval of the induction of abortion in cases of phthisis complicating pregnancy.

PSYCHOLOGICAL MEDICINE.

THE quarterly meeting of the Royal Medico-Psychological Association was held at the House of the British Medical Association on February 16th. The President, Sir FREDERICK MOTT, announced, with great regret, the death of Dr. Henry Rayner, of whom a memoir appeared in our issue of February 20th (p. 351). During his long life Dr. Rayner had been general secretary, president, and editor of the journal of the association, and in many other ways had rendered it great service. Dr. PERCY SMITH spoke of the valuable work of Dr. Rayner, not only for that association, but also for the Mental After-Care Association, of which he was for many years chairman, and to which he had made a donation of £500 three days before his death. Dr. Rayner had started the first out-patient department for mental diseases in association with a general hospital—namely, at St. Thomas's. Reference was also made to the very recent death of Dr. Moore of the Virginia Water Sanatorium, of whom we published an obituary notice on February 20th (p. 353). The PRESIDENT also congratulated Professor G. M. Robertson, a past president of the association, on his election as President of the Royal College of Physicians of Edinburgh.

Haemoclasia in the Psychoses and Encephalitis Lethargica.

Dr. ISABELLA ROBERTSON read a paper on the blood and vascular conditions in psychoses. She described observations on the occurrence of the haemoclastic crisis in psychoses, and investigations as to the effect of hyoscine and adrenaline on the production of that crisis in encephalitis lethargica. She contended that the reaction was a true one, and was not related to such factors as normal variations in the leucocytes. She had shown that reversals of reaction occurred under the influence of sympathetico- and parasympathetico-ministic drugs. This crisis was characterized by leucopenia, fall of blood pressure, inversion of the leucocytic formula, hypercoagulability of the blood, and diminution of the refractive index of the serum. To demonstrate its presence 200 grams of milk was administered to a patient who had fasted since the previous night. The total and differential leucocyte count and the blood pressure were noted before the milk was taken, and at intervals of twenty, forty, and sixty minutes after it. The maximum disturbance occurred generally at the forty-minute interval. In 50 well marked cases of dementia praecox of all types and at all ages, 91 per cent. reacted to the ingestion of milk by a definite haemoclastic crisis. In 70 per cent. of these the leucopenia was accompanied by a fall in blood pressure of from 3 to 12 mm. of mercury. In cases of melancholia, acute and chronic, 75 per cent. definitely showed the crisis, 15 per cent. a normal leucocytosis, 10 per cent. an indeterminate result; 55 per cent. of the mania cases examined showed the haemoclastic crisis, 20 per cent. gave a normal leucocytosis, and 20 per cent. an indecisive result. Dr. Robertson commented on a paper by Dr. A. F. Bernard Shaw (*JOURNAL, May 16th, 1925, p. 914*) in which the crisis was discussed as a test for liver function, with special reference to leucocytic changes. The paradoxical results which Dr. Shaw obtained were, Dr. Robertson said, similar to those which she had obtained and termed intermediate. She found that the general effect of heat in normal subjects was to

cause a leucocytosis, but if the heat was intense a leucopenia was found. Similarly, ordinary cold caused leucopenia, but if prolonged a leucocytosis occurred. The leucocyte count could be affected by psychic and emotional disturbance, and the variations might be both rapid and intense, but with care and proper technique it was possible to obtain leucocytic equilibrium within an hour. Of 275 early psychotic cases investigated, ranging from the milder neuroses to the more acute forms of mental trouble, 49 per cent. showed the haemoclastic crisis, 12.5 per cent. gave an intermediate reaction, and 38.5 per cent. reacted normally by a leucocytosis; 50 per cent. of the intermediate ones showed the haemoclastic crisis later. She gave some tables of results, and said there seemed to be some prognostic value in the presence or absence of the crisis in these cases. Investigations on the ingestion of milk following the administration of adrenaline, atropine, and pilocarpine respectively showed that adrenaline and atropine could convert the leucopenia into a leucocytosis, while neither had any influence on the leucocytosis occurring in the normal subject. The effects of pilocarpine were too varied to permit of a statement being made. Administration of thyroid extract caused a reversal of the reaction; it produced the crisis in a normal subject. Dr. Robertson said that 13 of 15 cases of encephalitis lethargica reacted to ingestion of milk with a definite leucopenia, the other 2 with leucocytosis. Subcutaneous injection of hyoscine in the encephalitic cases caused a leucopenia in all except one. In the cases of chorea the drug was followed by a marked leucocytosis in 4, a slight leucocytosis in 1, and a leucopenia in 1. Thus the tendency was for the effect of hyoscine to resemble that of the response to milk, though this did not hold absolutely. In the investigation of anaphylaxis it had been established that certain phenomena occurred at the time of, or just preceding, the onset of anaphylactic symptoms. The most important were a fall in the leucocyte count, a drop in the arterial blood pressure, a hypercoagulability of the blood, and a diminution of the refractive index of the serum. This crisis was demonstrated in asthma, paroxysmal haemoglobinuria, epilepsy, and other conditions. Anaphylactic shock, Dr. Robertson said, was not due to a specific poison, but could appear as a result of a physical process. Schiff had shown that a marked eosinophilia occurred in the blood during anaphylactic shock. There seemed to be a marked similarity between haemoclasia and anaphylaxis. Gluser had found that after an active dose of adrenaline or atropine the leucopenia following the ingestion of milk could be converted into a leucocytosis, and that in a normal person pilocarpine converted the leucocytosis into a leucopenia; his conclusion from this was that the haemoclastic crisis was a change in the equilibrium between vagus and sympathetic tonus. Haemoclasia occurred after glucose in practically every case of diabetes, but after the ingestion of milk in less than 50 per cent. Summarizing, Dr. Robertson said that haemoclasia occurred in 94 per cent. of cases of dementia praecox, in 85 per cent. of melancholias, in 75 per cent. of manias, and in 88 per cent. of encephalitis. The blood changes were in the venous blood as well as that in the periphery. Her suggestion was that a condition of anaphylaxis existed in cases who showed haemoclasia, and that this condition depended on the condition of the sympathetic nervous system.

Dr. F. L. GOLLA thought Dr. Robertson was correct in saying that the haemoclastic reaction could be obtained with unfailing accuracy when certain precautions were observed, but those who hoped to discover by this reaction some form of mental or nervous disease were doomed to disappointment. It was a simple phenomenon, uncomplicated by the ingestion or absorption of foreign proteins. In one case Dr. Robertson had found that there was a different reaction according to whether the patient was standing up or lying down, and reversals could be obtained by administering adrenaline or thyroid extract. The bronchi and the musculature of the lungs were also involved in the reaction. If the bronchi were contracted, as in asthma, there was one type of reaction; if they were dilated, the type was reversed, and the same was true of the sympathetic nervous system elsewhere. A minute dose of adrenaline caused relaxation, a larger dose was

followed by constriction, and the reactions depended also on the state of the receptive organ. The reaction was not diagnostic, but it showed that an organ was in a certain state of either equilibrium or dysequilibrium. It also seemed that the test would be of value in prognosis. At the bottom of nervous conditions there seemed to be a maldisposition of the vegetative nervous system.

Dr. A. A. W. PETRIE said that many anxiety cases gave a positive reaction, perhaps largely because these patients returned to the Maudsley Hospital after a trying time at home, so that they came in a state of exacerbation. A very high proportion of cases of dementia praecox gave the reaction. He agreed with Dr. Golla that the test promised to be of great assistance in the matter of prognosis; it might show with fair truth what cases were likely to pass into the certifiable stage.

The PRESIDENT said this was a very important study, indicating the dysequilibrium of the vegetative nervous system which was common to all cases of psychosis. Owing to a change in the hydrogen ion content of the blood, he thought the surface tension of the fluid might be altered, so that the leucocytes adhered more to the sides of the vessels.

SARCOMA OF THE UTERUS.

At a meeting of the Section of Obstetrics of the Royal Academy of Medicine in Ireland on February 5th, the President, Dr. D. G. MADILL, in the chair, Dr. GIBBON FITZGIBBON showed three specimens, one of which was a sarcoma of the body of the uterus.

Dr. FitzGibbon stated that these specimens had been removed from patients aged 45, 43, and 44 respectively. The sarcoma specimen had been removed from a patient married for twenty years, with two children aged 19 and 10 years; she had been a widow for the past ten years. The other uteri were from women, one married twenty years with one child aged 18, the other woman married a few years and with no children. The symptom in each case was profuse haemorrhage for a few months at intervals suggestive of irregular menstruation, which they had all ascribed to the onset of the menopause. None of the patients suffered any pain, but all had been debilitated by the haemorrhages. The specimen of sarcoma showed a large nodule projecting into the uterine cavity from the fundus, and the growth had invaded the uterine wall deeply. Microscopically the tumour was a round-celled sarcoma; in some places the cells were very diffuse, in others relatively compact. It was difficult to say whether the growth originated from the uterine wall or the endometrium. The whole uterus was enlarged, with a thickened wall, and considerably softened.

The interest in the three cases was the close resemblance of clinical symptoms and the almost identical physical signs obtained by vaginal examination. There was nothing to distinguish the sarcomatous case from the others until the uterus had been removed and examined histologically. The cases illustrated the necessity of looking upon all cases of severe bleeding at the time of the menopause with suspicion and not temporizing in treatment.

The PRESIDENT said that sarcoma of the uterus was rare compared with carcinoma of the uterus, and he had only seen a few cases of sarcoma. In one case the growth looked like an ordinary fibroid polypus, but when removed it was found to be fibrosarcoma. A second case was practically identical, and in both a radical operation was performed; both patients did very well. Sarcoma was supposed to be a rare condition, but he thought that if every fibroid was examined the percentage of sarcomata would probably be higher than was generally thought.

Dr. BETHEL SOLOMONS said he had removed a uterus ten days previously which resembled the uterus under discussion. The patient, aged 50, had been seen by him in November; she had suffered from haemorrhage and had been curetted for diagnosis; further operation or treatment was at the time refused. She returned later, however, and asked for further treatment. She measured 60 inches round the abdomen and the vagina was very narrow. Vaginal operation was impossible, not only on account of this, but because of the size of the uterus. The growth seemed to

be too extensive for radiation, and the operative results and prognosis in body cancers were excellent. He had decided to perform a total hysterectomy through a Pfannenstiel incision; the operation had been difficult, but was brought to a successful conclusion. He did not think a Wertheim operation was at all necessary in this type of case. In his experience sarcoma of the uterus was a disease of the menopause.

Dr. FITZGIBBON, replying, said that possibly a small number of fibroids were sarcomatous, but he did not think that many were. He never thought of doing Wertheim's operation; he always did complete hysterectomy. He looked upon Wertheim's procedure as unnecessarily severe, and believed that as good results were obtained from hysterectomy. He would never advise radiation in these cases as he did not see how radium could get to the tumour if this had penetrated the uterine wall and invaded the perimetrium.

ULSTER MEDICAL SOCIETY.

At a meeting of the Ulster Medical Society, held in the pathological laboratory of the Queen's University on February 18th, with Dr. DARLING, ex-president, in the chair, Professor SYMMERS showed a large number of pathological specimens, among which was a brain tumour, the size of a Tangerine orange, found in the right frontal region of a girl who presented no symptoms except headache. Professor T. H. MILROD explained some researches which he had been carrying out in his laboratory on the influences of phosphates on carbohydrate metabolism. Dr. T. HOUSTON demonstrated: (a) phagocytosis of red blood cells, and (b) Sir Almoth Wright's slide cell technique. Dr. V. D. ALLISON showed: (a) section of actinomycosis of chest wall, and (b) slides of Ducey's bacillus, *B. welchii*, *B. tetani*, Vincent's angina, and rat leprosy. Dr. R. H. HUNTER showed some modern histological methods for nerve tissue. Dr. SIMMS showed a specimen of cirrhosis of the liver found in a child aged 9; microscopic slides showed intercellular cirrhosis, and Professor SYMMERS said that the case was undoubtedly syphilitic. Dr. I. H. McCRAW showed slides and culture of ringworm fungi. Dr. J. W. ORR related some experiments as to the cause of cholelithiasis, and exhibited preparations showing lipid deposits in human and animal gall bladders under normal and experimental conditions, and also inflammatory margination of leucocytes. Dr. A. E. CAMPBELL exhibited sections of liver and kidney showing fat changes in diabetes mellitus; with the administration of insulin the fat had practically disappeared from the liver, but the kidney was still filled with it. Mr. J. S. CAMPBELL showed an ovum of *Trichocephalus dispar*, and films from bone marrow in a case of aplastic anaemia. Dr. LOUGHRIDGE made some observations on recent work on the removal of parathyroid glands and treatment; dogs suffering from the symptoms of parathyroid removal were immediately cured by a parathyroid extract—as dramatically as comatose diabetic patients were by injection of insulin—and these dogs could be kept alive and well for months by repeated injections.

After the formal papers and remarks, Professor SYMMERS praised the research work which had been demonstrated, and the various exhibitors then personally explained the preparations to a succession of small audiences.

NOTTINGHAM MEDICO-CHIRURGICAL SOCIETY.

At a meeting of the Nottingham Medico-Chirurgical Society on January 21st, Mr. H. BELL TAWSE, the President, in the chair, Sir WILLIAM MILLIGAN read a paper on radio-diathermy in the treatment of inoperable malignant diseases of the upper air and food passages. The paper is published in full this week at page 364.

In the subsequent discussion, the PRESIDENT suggested that in many of the cases considered operable a better result would be obtained from diathermy than from surgery; an operation often revealed extensions which placed the cases in the inoperable category. Even though in rare

cases, for some unknown reason, both radium and diathermy seemed to stimulate the growth of malignant disease, yet the excellent results were numerous enough to overshadow this completely. He advised a preliminary gastrostomy when dealing with malignant oesophageal stricture and in diathermy of hypopharyngeal growths if these were considered worth treating, which he doubted.

Mr. F. CROOKS discussed the application of diathermy to malignant disease of the skin, and mentioned difficulties he had encountered with necrotic bone underlying extensive rodent ulcers. Mr. R. G. HOGARTH raised the question why diathermy was not more frequently used in malignant disease elsewhere if it was so useful in this locality. Dr. F. H. JACOB commented on the "cancer phobia" likely to be produced if cancer weeks were established. Mr. A. R. TWEEDIE drew attention to the length of time necessary for the separation of sequestra. Dr. STANLEY GREEN believed that there was a great future for radium and diathermy, both separately and combined.

JAMES MACKENZIE INSTITUTE FOR CLINICAL RESEARCH.

VITAL ACTIVITIES IN THE HUMAN BODY.

CONTINUING the consideration of Sir James Mackenzie's recent work, Professor DAVID WATERSTON opened a discussion at the James Mackenzie Institute for Clinical Research, St. Andrews, on the vital activities of the human body. The biological principle postulated was that a living cell was never at rest, but was engaged either in discharging energy, in the shape of its function, or in renewing its energy. Modifications of the activity of cells—increased or decreased activity—depended upon the rate of the renewal of energy, which could be accelerated or retarded, while the time occupied by the discharge probably remained constant. Contractile tissues such as muscle, the walls of capillaries, and the genetic tissue of the heart, contracted only in response to impulses from other structures. Thus voluntary muscles contracted in three different ways: first, from impulses from parts of the central nervous system; secondly, by impulses from other sources when it was quiescent, giving rise to that form of contraction termed "tone"; thirdly, by impulses reaching the muscle from other sources when it was severed from its nerve connexions, giving rise to the form termed "fibrillation." In nerve cells there were specially developed the functions of impulse production and conduction. The afferent fibres or dendrites of such cells received the impulses which act upon the cell, hastening or delaying the renewal of its energy, and so hastening or retarding the production by the cell of an impulse which travelled away from the cell by the axon fibre. Further, the impulse received from the discharging fibrils the quality which either hastened or delayed the recovery of the cells with which it was in contact. It could be shown that atropine, for example, acted by paralysing the terminal discharging fibrils of the vagus, which ordinarily retarded the renewal of energy in the cells of the *s-a* node, and so atropine increased the rate of the heart beat. Digitalis, on the other hand, acted upon those receiving fibrils which accelerated the activity of the vagus cells. Digitalis thus increased the activity of the vagus, and so slowed the heart rate.

Finally, the activity termed "control" was discussed. This (Professor Waterston said) was an influence exercised by cells of "higher" type upon other cells or tissues, whose presence was realized only when it was withdrawn. Apart from the "control" exercised by nerves over the organs with which they were connected, control was well illustrated in the heart. The *s-a* node controlled the *a-r* node. When its control was removed the *a-r* node was rendered more sensitive to other impulses. Hence, in auricular fibrillation, when the *s-a* node was out of action, there was a disproportionate increase of the heart rate on effort, and undue retardation by digitalis from excessive alterations in the activity of the *a-r* node. The genetic tissue controlled the ventricular muscle. When its influence was lost the ventricles passed into fibrillation.

Reviews.

THE TREATMENT OF DIABETES.

MANY articles and books have been published dealing with the treatment of diabetes since insulin was first discovered in Toronto. But the work of Banting and his colleagues was so well and carefully carried out that other writers have really little to say except to admit that when they follow Banting's advice they can reproduce Banting's happy results. The literature that has come from Toronto dealing with insulin has been remarkable throughout for clarity and brevity. CAMPBELL and MACLEOD have published a monograph of 200 pages, *Insulin and its Use in the Treatment of Diabetes*,¹ giving an adequate account of the experimental work which led up to the preparation of insulin, together with a clinical section that presents to practitioners the best guide to the therapeutic administration of insulin that we have seen.

The first seven chapters deal with the physiology of the subject and such aspects of the experimental work as bear directly on the clinical use of insulin. These chapters are full of interest even to readers who have forgotten most of their physiology. The remaining nine chapters contain in the small space of 138 pages a little gold mine of practical information in most readable form.

The authors lay stress once again on the futility of all methods of administering insulin except by hypodermic or intravenous injections. They further observe that when the insulin requirement exceeds 40 to 50 units, as may happen, it is usually better to divide the day's allowance into three or more doses. This is a suggestion of the greatest possible value, which seems scarcely well enough known. When the daily requirement exceeds 10 units they found the single dose method unsatisfactory. On the subject of undernutrition, Dr. Campbell is arrestingly explicit: "that marked undernutrition possesses any mysterious benefits for the patient who has sufficient tolerance . . . I frankly do not believe." He lays down as one of the Toronto principles of treatment, "adequate nutrition and sufficient food on which to do light work."

Another dictum worth remembering is "that glycosuria in diabetes is a failure in treatment," and, according to Toronto teaching, it should be avoided: in this connexion Joslin is quoted—"a sugar-free urine is just as necessary with diabetics treated with insulin as diabetic cases treated without insulin."

Campbell insists that in treating diabetes it is hyperglycaemia, not glycosuria, that is the enemy to be combated. He speaks scornfully of those whose convictions permit glycosuria in the diabetic as naturally having no trouble about maintaining normal blood sugars. It is hyperglycaemia which overstimulates the pancreas and, as Campbell believes, diminishes the prospect of permanent improvement under insulin treatment. Many doctors, and patients too, are afraid that the continuous use of insulin may lead to an impairment of its value so that the dosage may need to be constantly raised. Three years of experience shows this to be entirely fallacious.

The short chapter on ketosis, acidosis, and coma explains the part played by accurately balanced diet in preventing these accidents. Insulin does not cure coma—it enables coma to be cured by carbohydrate; or in Campbell's words, "carbohydrate must be available . . . to burn up the ketones." "This is provided by giving the patient 1 gram of sugar for each unit of insulin." It might be more correct to say, 1 unit of insulin for each gram of sugar.

On dietetic methods the Toronto General Hospital scheme is given in full detail. The plan is based on providing a patient from the outset with an adequate minimal diet for maintenance. There is no question of starvation, of fast days, or "ladder" diets. Just enough food, with the fat, carbohydrate, and protein properly balanced, and then—

the insulin has to be made to fit the diet. The superiority of this plan over all others cannot be too widely acknowledged.

This book will rank as the standard work on the treatment of diabetes by means of insulin, and should be read by every practitioner in the English-speaking world.

The concise and practical manual by Dr. R. D. LAWRENCE entitled *The Diabetic Life*² aims at bringing the modern treatment of diabetes within the scope of the general practitioner. We are not quite convinced that its claim to enable the busiest doctor to start accurate treatment without any elaborate calculation of diets and food values is well advised. In our experience it is far wiser that the medical profession should realize once and for all that if insulin is to be used successfully the principles underlying the calculation of diets and food values have got to be understood. Even Dr. Lawrence's "explanation to doctors" of his "line-ration" diet scheme on page 41 demands some knowledge of the principles at least on which the calculations are based. The author is not quite in agreement with those authorities who advocate putting the patient at once on a permanent maintenance diet; he prefers, as he says, "to obtain the beneficial effect of slight undernutrition." It is true that he does not pursue this plan if the patient is seriously emaciated. We are not at all persuaded of the beneficial effect of slight undernutrition except in cases that do not really require insulin at all.

Moreover, on analysing the "line-ration" method ration by ration it appears that the fat allowed is rather higher than Woodyatt's formula of $F = 2C + \frac{P}{2}$, since with a diet of 1,900 calories we find that he counterbalances 150 grams of fat by only 50 grams of carbohydrate and 75 grams of protein. This excess of fat may in some diabetics be sufficient to cause ketosis. It is fair, however, to add that in the "explanation to doctors" the advice given is "if acidosis is severe the fats can be cut out." This is referred to in further detail on page 56, but the reduction of fat is not put on a sufficiently scientific basis for the delicate metabolism of a severe diabetic. The author remarks here that "fat is the most economical foodstuff in its insulin requirements"; he does not, we venture to suggest, lay enough stress on the fact that it is the most exacting in its glucose requirements. The "5-gram" system possesses many advantages over the "line ration," chiefly because of the greater choice of food it allows. It is really simple enough to be used from the outset. But it would be still further simplified if the patient bought a machine that weighed the food in grams, as advised on page 113. Half the troubles of diabetic diet arise from retaining ounces in our diet tables. Dr. Lawrence is generous in his protein allowance for diabetics, as he permits 100 grams of protein in a diet of 2,040 calories given in example 1 on page 131.

The best chapters in the book are those which deal with complications, pregnancy, and operations. As suggested in Professor Nixon's lecture and a leading article published a few weeks ago (*BRITISH MEDICAL JOURNAL*, January 16th) the practical importance of these subjects makes them worthy of careful clinical study, and Dr. Lawrence is to be congratulated on the concise and valuable advice he gives upon them. He does not perhaps lay sufficient stress on the need of increasing the carbohydrate intake when tiding a diabetic through an operation. When all is said and done it is sugar that a diabetic needs, and insulin is only the means whereby he is enabled to make use of it.

The food tables given at the end of the book are full, varied, and excellently set out. The tables of average weight at given heights and ages will be found most helpful. It is better to diet a diabetic according to some ideal weight than to diet him according to his present state, which may be grossly fat or miserably thin.

The book is well written and well printed, while its price is commendably small in these days.

INCAPACITY IN ITS MEDICAL ASPECT.

It is becoming almost a trite observation in the law courts, especially in those dealing with cases under the Workmen's Compensation and Employers' Liability Acts, that doctors can always be got to support either side on medical questions. This by no means always insinuates anything more than honest differences of opinion, and though these differences will never be entirely removed it is clear that books written by men of wide experience, such as Dr. BROCKBANK'S *Incapacity or Disablement in its Medical Aspect*,³ have a wide scope of utility. In the National Health Insurance medical service also differences of opinion are constantly arising between approved societies and panel doctors as to whether insured persons claiming sickness benefit are or are not incapable of work. This is shown by the fact, quoted by Dr. Brockbank, that in the year 1924 the cases of doubtful incapacity for work referred to the regional medical officers for decision numbered 186,115. Of this number, 81,250 individuals failed to attend for examination and were struck off the funds, and of the 102,596 actually examined 77,935 were found incapable of work and 24,661 not incapable of work; presumably all the 24,660 had been certified as incapable; in some cases it is possible that the certificates had been given without proper examination, but no one who has not had to deal with the insured can imagine how extremely difficult it often is to decide whether a patient is or is not incapable of work. The certificate required to entitle to sickness benefit simply states that the person is "incapable of work," not that he is incapable of following his usual work; and though the Minister of Health gives no legal definition of incapacity, the approved societies generally agree that for sickness benefit it is not essential that the insured person should be totally incapable of doing any work of any kind. "Continuation certificates" have to be provided at fixed intervals during incapacity, but one of Dr. Brockbank's statements needs some modification—namely, that when a doctor considers that the patient is fit for work he does not say so on the certificate, but simply ceases to give any certificate, and benefit then automatically stops. Now, though it is quite true that benefit stops when certificates are not produced, the panel doctor is instructed that, as soon as he finds the person is fit for work he must issue what is known as the "final certificate," which states that the patient "will be fit to resume work after to-day" (or on a date not later than the third day after examination); and insured persons are definitely ordered "to be careful to obtain a final certificate before resuming work."

A specially interesting part of the book is a description of the different points of view as to partial or total incapacity taken by workmen on the one part and employers or insurance societies on the other. The definition and implications of the term "accident" as understood under the Workmen's Compensation Act and the Employers' Liability Act are fully discussed, and numerous decisions of the courts, remarkable for their curious inconsistency, are quoted. A useful classification is given of the different forms of labour according to the different degrees of effort and endurance required, and the term "fit for light work only" is considered.

The second section begins with brief indications of the value to be attached to subjective as contrasted with objective signs and the effects of pre-existing disease in causing disablement after accidents. The remainder of the book discusses in alphabetical order all the ordinary medical and surgical diseases so far as they affect incapacity for work, and special attention is devoted to heart diseases, high blood pressure, and arterio-sclerosis. The reputation of the author, not only as honorary physician of the Manchester Royal Infirmary, but as a recognized expert in life assurance examination, is in itself a guarantee of the soundness of the opinions expressed, and an added value is given by the frequent quotation of decisions of the law courts already mentioned, which, though not always in strict accordance with the best medical evidence, must needs be accepted as reflecting the overruling public opinion

as to the effects of accidents and diseases on incapacity for work.

There is a serious economic—or shall we call it an ethical?—aspect of the decisions of the courts. It is commonly believed, rightly or wrongly, that there is some tendency generally to favour the claims of the workmen under the Compensation and Liability Acts. Will this not inevitably drive insurance societies to reject or only to accept with an almost prohibitive premium men suffering from even slight disabilities? It is saddening to note how frequently war pensioners complain that they are refused work when it is known that they have a pension for even small disabilities, such as slight D.A.H., myalgia, or slight rheumatism, and especially neurasthenia. The mere fact that a medical board has decided to recommend them for a pension, though it may be on the "less than 20 per cent. scale," is sufficient to ensure their rejection by employers of labour, who fear loss of time or claims for deterioration through work which would not affect an ordinary man. Whether we like it or not, it is a fact that patriotism is very often outweighed by balance sheets. The problem is increasingly difficult, and Dr. Brockbank begins at the foundation by attempting from a medical point of view, and with a considerable degree of success, to show how far the various forms of medical and surgical disabilities really do cause or tend to cause total or partial incapacity for work.

OBSTETRICS AND GYNAECOLOGY.

Books of the type of *Recent Advances in Obstetrics and Gynaecology*⁴ are of periodical use and value to all interested in the subjects, and Mr. A. W. BOURNE'S volume will repay perusal. In the first portion of the book, devoted to obstetrics, pride of place is rightly given to ante-natal care. Then follows a chapter in which the persistence of the maternal mortality of childbirth is considered. The basis of this is Dr. Janet Campbell's report on the subject to the Ministry of Health, and it would appear that the editor has either not read or not taken into consideration the report of the Scottish Commission which investigated the same subjects. This omission decidedly diminishes the value of the chapter, as the Scottish Commission's report contained several suggestions of positive value in regard to the prevention of mortality. The interim report of the committee of the British Medical Association was, of course, issued too late (SUPPLEMENT, January 9th) to be noticed in this volume. The causation of stillbirth is considered in the light, mainly, of the work embodied in the reports of Dr. Holland and Dr. F. J. Browne to the Medical Research Council. Following this there is a chapter which summarizes clearly much of the work of the last few years on the chemistry of the blood and urine in pregnancy. The pathology and treatment of ante-partum haemorrhage, the prognosis and treatment of eclampsia, and the scope, results, and risks of Caesarean section are all adequately discussed. The chapter on puerperal sepsis which closes the obstetrical portion of the book is largely based on the material which came before the Obstetrical and Gynaecological Congress last year, but this is competently analysed.

The gynaecological section of the book opens with a chapter on prolapse, for the treatment of which the author favours the Fothergill operation. Myomectomy, ovarian grafting and conservative operations upon the ovary, varicocoele of the broad ligament, and retroversion are all discussed, and the author speaks of the "more rational attitude now manifested to the curette." In dealing with so-called "functional menorrhagia" the influence of the endocrine glands upon gynaecological conditions is discussed. The section upon sterility is mainly concerned with the inflation of the tubes. A chapter on endometrioma of the ovary was inevitable, and it summarizes our present knowledge of the subject. Dr. J. H. Douglas Webster has contributed a most admirable chapter upon the use of x rays in obstetrics and gynaecology, which will be read with interest and appreciation by all gynaecologists. Dr. Justina Wilson supplies a suggestive chapter on electro-

³ *Incapacity or Disablement in its Medical Aspect*. By E. M. Brockbank, M.B.E., M.D., F.R.C.P. London: H. K. Lewis and Co., Ltd. 1925. (Demy 8vo, pp. viii + 120. 7s. 6d. net.)

⁴ *Recent Advances in Obstetrics and Gynaecology*. By Aleck W. Bourne, B.A., M.B., B.Ch.Camb., F.R.C.S. Eng. London: J. and A. Churchill. 1926. (Extra post 8vo, pp. vii + 344; 58 figures. 12s. 6d. net.)

therapeutics in gynaecology, and Mr. Malcolm Donaldson discusses radium in the treatment of carcinoma of the cervix, a matter to which he has devoted very close attention and study. Here the question may arise in some minds whether the intra-abdominal application of radium by Daels's chains should strictly be described as an "advance." The book finishes with a short appendix illustrating some of the gynaecological instruments which have been put on the market in the last few years—some of them constitute advances, but others scarcely come into that category.

The book is on the whole useful and readable, and Mr. Bourne will receive the thanks of many of his colleagues for the work which he has put into it.

Dr. WANLESS DICKSON'S *Rational Gland Therapy for Women*¹ is a small, pleasantly and plausibly written monograph of 96 pages, in which is presented much of what passes current for knowledge of the influence of the ductless glands in pregnancy and in gynaecological conditions. The bulk of this so-called knowledge is, of course, purely speculative, but the trend of the teaching in this book is to speculate first and watch the results. "The writer, all through his searchings after truth in the realm of organic therapy, has followed the advice of the great John Hunter—'Don't think—try.' " This somewhat ambiguous confession will be interpreted differently by different readers. The writer's credulity and enthusiasm seem to be boundless, as witness a case of membranous dysmenorrhoea "seen by the writer during the paroxysm of pain during an attack. Before the membrane was expelled, she was given by the mouth five grains of corpus luteum. Within ten minutes there set in a violent uterine haemorrhage. This was controlled by the exhibition of twenty grains of mammary substance." The italics are the reviewer's.

PRACTICAL PATHOLOGY.

ONE of the most popular books in the Edinburgh Medical Series has always been Dr. MILLER'S *Practical Pathology*, and we are glad to see that a second edition² has been issued. Two special characteristics of this book—its brief, easily memorized descriptions and the rich store of practical detail it contains—have endeared it to two different classes of readers, the student preparing for examinations and the working pathologist looking for advice in the technicalities of morbid anatomy and post-mortem work. Student readers have found the lavish collection of photographs bound together at the end of the book a particularly helpful feature. The other class of reader has turned more frequently to the appendix or to Chapters III and XV, which deal respectively with the removal of the different organs in post-mortem examinations and the examination of cases with a medico-legal aspect. The general arrangement of the book and sensible use of different types enable the student who is beginning his pathological studies to distinguish the less from the more important.

The *Handbook of Pathology*,³ by Dr. C. Y. WANG, professor of pathology in the University of Hong-Kong, is an examination textbook for medical students. The first impression received on turning over the pages is that this comparatively short book is designed on the synopsis plan, for which certain types of students have a preference, but which to the more leisurely reader is a defect. This impression is removed on systematic reading: the descriptions are brief and concise, but embodied in properly formed sentences. Students will probably agree that the author's object has been achieved and that they possess in this book a convenient collection of facts required on the examination day. As to its general plan, the book is not separated into the customary divisions of general and special pathology, but is divided into chapters based on etiology, or on the character of tissue changes. Thus, lesions of similar or

allied nature are grouped together, their anatomical position being a secondary consideration. Great stress is laid on morbid anatomy throughout, and the 282 illustrations, most of them photographs, are a valuable supplement to the descriptions of naked eye and microscopic characters.

Some additions have been made to the second edition of Professor N. PH. TENDELOO'S textbook of general pathology,⁴ but it is not substantially altered thereby. The author takes a broad view of pathological problems, and his book affords evidence of experience gained in clinical practice as well as in laboratory work. He has succeeded in interpreting the science of pathology without dividing the subject into the customary general and special sections, and by means of cross-references and an exceptionally efficient index avoided the repetition and overlapping which the conventional method of division too often entails. Every pathological phenomenon has both a special and a general significance. Its special significance it owes to its difference from other more or less similar phenomena. Its general significance depends on its accord or its similarity with other phenomena from which it differs in certain particulars. Thus special pathology should seek to establish the special significance of pathological phenomena, and general pathology should look for the general significance and discover the laws by which events are governed. To succeed in expounding the doctrines in this unified form each subject must be viewed as a part of a larger, and its position as well as its character considered. From the educational point of view this method of treatment is undoubtedly the best, though such a book does not become a useful source for reference until the reader has learnt his way in it, and it will be chiefly in this capacity that this exposition of the science of pathology will be used in English-speaking countries. The book is well illustrated and has a respectable list of references.

"FAMOUS MEN AND OUR FATHERS. . ."

SIR OLIVER LODGE in his appreciative introduction to the Rev. ROBERT H. MURRAY'S *Science and Scientists in the Nineteenth Century*⁵ remarks: "It is not often that men of science are looked at with the eye of an historian, and their merits and demerits parcelled out with an impartial hand." This statement will perhaps startle those who are interested in the history of medicine, especially students of the late Sir Clifford Allbutt's and Sir William Osler's works on this subject. But perhaps this is only a method of recommending this scholarly work, which indeed is an extremely valuable and admirably written review, and full of stimulating suggestions. It is surprising to find such exact knowledge of medicine and science in a writer who is neither a professional scientist nor a member of our profession. Nettled by the assumption of some scientific writers that theologians are moved by preconceived ideas, whereas men of science are concerned only to find the truth, the author confesses in the preface that one of the main objects of the book is to show that there are as many preconceptions in science as there are in theology. Though the motive may be disappointing the information contained is none the less attractively set out, and there is not any undue emphasis of the preconceived notions of our profession. In successive chapters the great scientific figures, mainly in this country, are brought before the reader's eyes, but the accounts of the individuals stop ten years after the appearance of their chief contribution to knowledge. Jenner and vaccination, Simpson and chloroform, Sir Charles Lyell and uniformitarianism, Helmholtz, Joule and the conservation of energy, the precursors of Darwin, Darwin and evolution, and Pasteur and microbes are discussed in turn. The chapter on the precursors of Darwin gives the history of evolution, and, in passing, commendation to the work of Lamarck, whose career is described as one of the most remarkable in the whole

history of science in that, except for Kant, he is the sole example of a man whose leading contribution was brought out after the age of 50. The chapter on forgotten scientists contains much that is rather melancholy in its record of the struggles against the hostile opposition encountered by those fighting for the truth, and in the story of the bitterness of scientific controversies in the nineteenth century. Many examples are given of men who came before their time: Thomas Young, James Hutton, Kant who said so himself, William Smith the father of British geology, von Baer, Fabre, Mendel, and Marcus Antoninus Plencz, who prophesied the germ theory of disease a century before Pasteur. Although the author sighs at "the striking results of investigator after investigator washed in the waters of Lethe," he fears that even now a research work of the highest class may fail to secure recognition.

The Conquest of Disease,¹⁰ by Mr. DAVID MASTERS, also a layman, is written in a different style, more as a popular lecture or light journalistic contribution. It is introduced by Sir JAMES CANTLIE, who records the circumstances in which he left Charing Cross Hospital and London in 1887 to join Sir (then Dr.) Patrick Manson, whose portrait forms the frontispiece, to practise in Hong-Kong, where he had experience of a plague epidemic. Well illustrated and containing portraits of many famous men, such as Edward Jenner, Sir James Y. Simpson, Lister, Roux, Metchnikoff, and Shiga, as well as pathological conditions and means for preventing infection, this work delivers a sound message on a wide range of subjects and is well up to date.

THE HEART IN THORACOPAGI.

YSANDER's inaugural dissertation on double monsters,¹¹ at the University of Upsala, which is written in English, can hardly be expected to appeal to any but professed teratologists; they, however, will find that it embodies an excellent piece of original research. Having the opportunity of examining a human thoracopagus in an early stage of development (24 mm.), the author proposed to utilize it with a view merely of contributing to general knowledge of double monsters, but in the course of his investigations he found that certain morphological details did not agree with accepted ideas as to the formation of the organs involved in the anomaly—ideas based on the examination of full-term specimens. He was thus induced to give special attention to the thoracopagi in an endeavour to trace back the anomaly to its source, so far as that was possible in the human subject; he was fortunate enough to obtain three further specimens in early stages, one 8 mm. in length.

The point to which Ysander chiefly directed his attention was the structure of the compound heart usually found in these monsters. It will be remembered that double monsters are considered to result from a twofold process of fusion—a primary fusion depending as to its extent on the degree of fission of the embryo, and a secondary, mechanical fusion of certain of the organs of the two foetuses, due to their close proximity. It was held by Schwalbe, an authority on these deformities, that the compound heart of thoracopagi is produced by the secondary fusion of the normally developed hearts of the two foetuses. Ysander's researches lead him to dissent from this view, and he places the fusion at a much earlier period of development—previous, in fact, to the formation of the primitive tubular organ. Normally the primitive tubular heart is formed by the union of two tubes, placed symmetrically one on each side of the median plane. In the thoracopagus the two pairs of tubes face each other, and, according to Ysander, each tube fuses with the tube facing it in the opposite foetus, thus forming two primitive tubular hearts, each of which is derived from both foetuses—an anterior receiving the blood from an anterior part of the whole monster, and a posterior from the posterior part. The definitive compound heart results from the union of these two, already composite, tubular hearts.

NOTES ON BOOKS.

It is only for the pleasant and witty style of it, anything that comes from the pen of Dr. LEONARD WILLIAMS is usually worth reading. But when he writes a book with the title *Middle Age and Old Age*¹² the curiosity of the elderly traveller in this vale of tears is inevitably aroused. Is our author able to save us from anxiety as to whether our chest or waist measurement will bear the palm next time we face our tailor? Can he help us to postpone the later stage of the lean and slippered pantaloons? For although we are told proverbially—and it is needless to say that the adage applies only to the laity—that a man of 40 is either his own physician or a fool, all of us know many in the circle of our lay acquaintance who manage quite successfully to be both. And the advice of cheerful centenarians to the multitude who aspire to follow in their footsteps is, as gathered from the contemporary daily press, somewhat contradictory. One old gentleman assured us lately (with the aid of a local reporter) that he attributed his healthy and lengthy years to the free and constant consumption of beer and black twist; another to the fact that he did not use (and never had used) either; and we are thus faced with a nasty *plus* and *minus* effect which is distinctly disquieting. A book such as this can be of advantage, not merely to the medical profession, but also to untrained entrants for the patriarchal stakes. Throughout Dr. Williams's advice is sane and sound, pleasant to read, and (granted the necessary will power) easy to follow. In seven chapters and less than 300 pages he deals with the fundamental errors that tend to prevent us attaining a ripe old age. "The endocrinology of the plateau" and "Red lights" are, perhaps, the two most interesting and instructive chapters in the book. "The summit plateau" is defined—*chen! fugaces*—as extending from the ages of 50 to 45, and in dealing with its endocrinology a large number of hints are given for the benefit of those who are not beyond the stage of benefiting by them; while others must be content to be warned by the danger signals, or exercise a Napoleonic stoicism in "the last phase." This is undeniably a book that should be on the shelves of every general practitioner.

Whenever the question of communicable disease in the tropics is dealt with we are sure to find among the preventive measures proposed a suggestion to the effect that "educational and propaganda work should also be undertaken," but we are rarely told how this should be done, the statement being left more or less vague. The native, up to the age of puberty at least, is bright and learns readily, and the value of *An Elementary Course in Tropical Hygiene*¹³ for children at the receptive age is considerable, in that the lessons inculcated at such a time will probably have a lasting effect. Dr. MARY BLACKLOCK has written such a course, dealing in simple language with the harmfulness of dirt, mosquitos, flies, rats, and so forth, and driving home to the child's mind by means of a story with several morals the lessons of the beauty of cleanliness, the advantages of exercise, pure food and water supply, of antimosquito measures, and rat prevention. The children in the story were unusually fortunate in possessing complacent parents ready to comply without demur with the hygienic demands of their offspring. The primer has a brief foreword by Dr. ANDREW BALFOUR, and it certainly appears eminently suitable for implanting elementary principles in the minds of native children in all parts of the tropics.

In his book on *Scoliosis*¹⁴ Dr. SAMUEL KLEINBERG of New York gives to the medical and nursing world the fruits of his considerable experience. He states in the preface that the book is intended primarily for orthopaedic surgeons and secondarily for general practitioners and nurses and educators. It is for the last class no doubt that it has been thought advisable to include a pretty full and well illustrated section on the anatomy of the normal spine, thus saving reference to anatomical textbooks. There is little to be said that is new on the treatment of scoliosis, but what Dr. Kleinberg says is sound and the outcome of wide experience. He recognizes, as do all orthopaedic surgeons of experience, that little can be done in the direction of cure for cases with bony deformity, and he holds forth no extravagant prospects of improvement. The operative procedures which have been devised and practised for the fixation of the spine or the removal of unsightly

¹³ *An Elementary Course in Tropical Hygiene*. Part I. By Mary G. Blacklock, M.B., B.Sc., D.T.M. Preface by Andrew Balfour, C.B., C.M.G., M.D., B.Sc., F.R.C.P. London: J. Eale, Sons and Danielsson, Ltd. 1926. (Cr. 8vo, pp. 47. 1s. net.)

¹⁴ *Scoliosis: Rotary Lateral Curvature of the Spine*. By Samuel Kleinberg, M.D., F.A.C.S. New York: Paul B. Hoeber, Inc. 1926. (Med. 8vo, pp. xvi + 311; 140 figures. 6 dols. net.)

prominences are described and discussed, and the book may be taken as a safe guide to practice by both general practitioners and specialists. Whether it is so well fitted for the instruction of those who have not had a complete medical education must be doubtful. The technical merit of the illustrations is great, and the paper and printing leave nothing to be desired.

PREPARATIONS AND APPLIANCES.

Isacen.

Isacen (diacetyl-dihydroxyphenylisatine) is a new synthetic purgative prepared by Messrs. Hoffmann-La Roche (7 and 8, Idol Lane, London, E.C.3). The anthracene group of purgatives and phenolphthalein and its derivatives, which have a similar action, form the most widely used group of purgatives, but all of these drugs, both natural and synthetic, have certain disadvantages attending their use. The action of a series of phenolphthalein derivatives was investigated in the Roche research laboratories, and the compound isacen was found to be the most efficient derivative obtainable from phenolphthalein or allied compounds. The manufacturers state that isacen is an insoluble, odourless, and tasteless powder, which passes through the stomach unchanged, but that in the alkaline medium of the small intestine the acetyl groups slowly break away, and a slightly soluble compound is formed which produces a mild irritant action on the large intestine, thus producing purgation. Clinical tests have proved satisfactory, since none of the drug appears to be absorbed, and therefore no irritant action is produced on the kidneys, an effect which is liable to follow the administration of many of the purified active principles of the anthracene purgatives. The drug was found to be a reliable purgative and not to produce any intestinal pain or discomfort. From the reports by the manufacturers it appears that isacen is distinctly superior to other purgatives of this same class. The dose is 1/6 to 1/3 gr. to be taken at night.

VENTILATION AND ITS EFFECTS.

METHODS OF MEASUREMENT.

THE recently issued report on methods of investigating ventilation and its effects, by Dr. H. M. Vernon and others,¹ carries one step farther an inquiry initiated by the Medical Research Council into the principles of ventilation, the previous results of which have been published in the *Science of Ventilation and Open-air Treatment* by Leonard Hill and in the *Kata-thermometer in Studies of Body-Heat and Efficiency*.

The "kata-thermometer" (for short the "kata") was invented by Professor Leonard Hill "as an instrument designed primarily for the measurement of its own rate of cooling when its temperature approximates to that of the human body." To be more precise, it is a thermometer raised to a temperature of 100° F. and then allowed to fall to 95° F., the time of such fall being accurately observed. The kata-thermometer may be used either as a dry-bulb or a wet-bulb instrument. As a dry-bulb thermometer it indicates the rate of heat loss by radiation and convection, as a wet-bulb by radiation, convection, and evaporation; the difference, therefore, between the two readings indicates the rate of cooling due to evaporation alone.

The sheltering effect of clothing on the body may be imitated by enclosing the kata in a wool finger-stall and comparing the cooling due to evaporation in the covered and in the uncovered condition respectively. When the heat loss from the uncovered kata promoted by fanning was increased by 146 per cent., the loss from a covered kata was increased by only 46 per cent.

The science of ventilation is one in which pre-eminently the comfort of the body is studied, for there is little use in supplying people with pure air if its temperature and its motion are such as to make them uncomfortable: they will not long endure a draught, however scientifically produced it may be. The comfort of the air of a room or of the atmosphere of any region depends very directly on the rate at which the heat leaves the body, whether too fast or not fast enough. Our own previous sensations as regards the rate of this heat loss must determine our opinion, for if we are already very hot, then the more rapidly our heat leaves us the more comfortable we shall feel; but, on the contrary, the colder we are already the more uncomfortable we shall feel. Clearly, the lower the temperature of the air, the damper this air, and the faster it moves, the more rapidly shall we lose heat. The report

before us is an attempt to bring to bear on these factors and their relationship to our sensations the accurate methods of modern physical measurement.

The report is divided into four parts, dealing respectively with the measurements of variations in the velocity and temperature of air currents; the calibration of the kata-thermometer; the influence of cooling power and of variability of air currents on sensations of air movements; and lastly, the influence of temperature, air velocity, and clothing on the rate of cooling of the human body.

A special form of thermopile and galvanometer, which responds more rapidly to changes of air temperature than does the mercury or the spirit thermometer, was devised. The workers found that many air currents were local, of short duration, and frequently vertical in direction. Neither the ordinary anemometers nor the kata-thermometer can register these brief, local currents; the kata is unsuitable because it takes at least a minute to fall through its prescribed range of temperature. The instrument devised was a hot wire, air-current detector on the following principle—namely, that "the convection loss from a heated wire is proportional to the square root of the velocity of the air current moving against it." The wire is electrically heated and is used in conjunction with a galvanometer from which all but 2 per cent. of the current is diverted. The details of this method of measuring air velocity are given on page 10 of the report. By the combined use of the thermopile and the hot wire detector much additional light has been thrown on the relative importance of temperature and of the movement of the air in the problem of ventilation.

In Part II Dr. Vernon records his studies of the calibration of the kata-thermometer, the report on which occupies ten pages. This involved calculating "the factor" of the kata, which, though theoretically constant during all ranges of temperature, is not actually so. The formula relating the factor (K) to the variables is—

$$K = 0.27 (36.5 - t) \phi;$$

where ϕ is the time in seconds required by the kata to cool from 100° to 95° F. in a still air chamber at a temperature t °. The factor represents the number of millicalories of heat given out by the kata in cooling from 100° to 95° F. divided by the surface area of the bulb expressed in square centimetres. Dr. Vernon found that the formula did not hold equally good through all the ranges of temperature commonly met with in factories. An "electric kata" shows a gradual rise in its factor at all temperatures. It was found that the factor varied by ± 0.34 per cent. for each degree above or below 57° F.

In Part III, which attempts to correlate cooling power and the variability of air currents with sensations, a classification of sensations had to be devised. The following was the ninefold scheme adopted: very stagnant; very stagnant to stagnant; stagnant; stagnant to medium; medium; medium to fresh; fresh; fresh to very fresh; very fresh. It was found that the various degrees of stagnation experienced in factory air were due entirely to differences of temperature, but that the degrees of freshness were due chiefly to variations in air velocity.

The cooling power of the kata combines these two variables better than any other device for measuring. A large number of factories were investigated. Some 229 observations were made in summer, and about 203 in winter, the mean results of which show that to produce a given sensation of air movement in winter required a cooling power about one unit higher than in summer. This difference is due to acclimatization; and the mean cooling power was found to change gradually from month to month as the mean temperature changed.

In Part IV the effects of temperature, air velocity, and clothing on the rate of cooling of the human body were worked out. It was found that the unclothed body would remain in temperature equilibrium at an air temperature of 81° to 83° F., whereas the warmly clad body would do so at 59° to 60° F.

The report concludes thus: "In order to induce an actual cooling of the overheated body of a man engaged in hot and heavy work, it is of most importance to reduce the temperature, and next in importance to reduce the clothing, whilst an increase of air velocity has but little effect."

HOSPITALS FOR THE MIDDLE CLASSES.

A SERIES of letters of exceptional interest, on nursing homes and private hospitals for the middle classes, has been published in the *Times* in recent weeks. The statements and opinions brought to light in this correspondence show that there is a good deal of dissatisfaction in the minds of all who are concerned in the existing provision for middle-class patients. The patients, the proprietors of the homes, and the medical profession, each complain. The patients (or their friends) complain because at a time of sickness, when income may be reduced, such heavy charges must be met. The proprietors of the homes complain that the criticisms directed against their charges are unjust, for these take no cognizance of the heavy costs of maintenance. The doctors complain that the equipment they need for their work, which is always at hand in the voluntary hospitals, cannot be got in the nursing homes. The complaints are just. They are not complaints against persons, but against a system—or, rather, a lack of system. Patients do find the charges of nursing homes heavy, and just when they are least able to bear them. The costs of nursing homes conveniently placed for doctors and patients are high, and must be high in order to maintain any fair standard of efficiency. They will be higher, as doctors insist on an equipment proper to their work. But even at these high levels they compare not unfavourably with the costs of well equipped hospitals when all fabric and establishment charges are properly included within their costs.

The trouble arises from natural causes: they are growing pains. A generation or so ago the middle-class patients—indeed, all except the poor—received medical and surgical treatment in their own homes. Domestic difficulties and surgical emergencies made "homes from home" necessities. The nursing home stepped into the breach. It was no more than a boarding-house or small hotel. Comforts were few. The heaviest charge, over and above the household cost, arose from the additional nursing staff, though this, save for a well trained and devoted hospital sister, was often amateur. The costs were then but little more than those of a hotel of similar class. But even so these weighed heavily upon patients, for illness comes unexpectedly, and is not, like holidays, well prepared for. In those days the nurses were untrained and had their quarters in the servants' rooms; now trained nurses are essential and they require their own rooms. Then operating theatres were unknown; now they are indispensable. Lifts and male porters were rarities; now they are commonplace. From all these causes charges have mounted, and will mount, for there are many necessities that have yet to come. To cite but two of these necessities: What place for modern treatment can be held complete that has no x-ray equipment? What surgeon feels content to leave a patient after operation within a home a mile away without a resident medical officer? These difficulties are inherent in the gradual adaptation of homely conditions to those required for quite other purposes. The problem at issue is how to meet these difficulties, how to provide these necessities, yet keep

the provision—nursing home or private hospital—within the means of those for whom it is intended.

In several of the letters published there are indications of the tendency of growth in middle-class provision. Larger nursing homes are displacing the smaller. Private hospitals, fully equipped, are being established on a co-operative basis, as at St. Chad's in Birmingham, or by means of private munificence, as at St. Thomas's, Guy's, the West London, and other hospitals; these again owe their formation to liberal benefactions. Such private wards meet many of the difficulties. Fabric charges do not appear, the cost of maintenance is reduced by combination with the larger and its resident staff are available. Thus charges are less and the service is of the highest. This development of private wards is comparatively new in this country, but it is the usual arrangement in the United States of America, where hospital practice most conforms to ours. The supporters of this development are many and increasing; but it has some antagonists, notably Lord Knutsford, who asserts that the voluntary hospitals are for the "sick poor," but even he concedes that the term is elastic. We may take it, then, that the voluntary hospitals are certainly being called upon to do more than they have done in the past, either as part of their ordinary work or by special arrangement.

It may be, however, that in the near future great changes are in store. New conditions are adumbrated in the administration of the Poor Law. It is possible that the infirmaries controlled by the guardians of the poor—who now, it should be said, for the most part work admirably—may be transferred to larger civic authorities that are free from taint of a long-past but cruel history. In such an eventuality it is almost certain that the municipal, or county, or State hospital will advance in status and in the confidence of both the public and the profession. Thus the call on the voluntary hospital for the treatment of the "sick poor" may be lessened. If events should so turn out, the natural corollary will be the further widening of the ambit of the voluntary hospitals, so as to admit in larger numbers middle-class patients who will pay for their maintenance and treatment. If this should come about it would be according to precedent. In other fields—notably education—private benefaction has shown the way to the State, and with development of State-aided provision the early benefactions have reverted to the use of the middle classes whence they originally came. Moreover, backed by the saying is, the middle classes are in truth the backbone of the country, and a provision that will meet the needs of these classes, and for which they are ready to pay, would be just.

Finally, the correspondence in the *Times* suggests means whereby payment may be made before the certainty of illness renders it imperative. Insurance is advocated. Trial has been made through the British Provident Association for Hospital and Additional Services, which owes its initiation to the work of the late Dr. Gordon Dill. Most citizens are familiar with the principles of insurance, and not least the middle classes. We insure our houses, and our furniture, our servants, ourselves against accident, and not lives for our dependants, and our car when we own one. Why not insure against the incidence of illness and its special costs? This is done to some extent. That it is so little done is because there is no sufficient

provision for any treatment beyond home treatment. If anything like the possibilities of a wider hospital treatment hinted at should come to pass, it is likely also that side by side with that growth the field would be explored by insurance companies, who know better than most the risks of sickness among their clientele.

Many questions of intricacy are involved in such propositions. One, and that not the least startling, would be the possible inclusion in the terms of any such insurance policy of a proviso that the insured shall submit to periodic medical examination, and to immediate treatment of any condition found likely to lead to illness, or the suppression of any habit or indulgence equally dangerous. This, however, would lead to a control, or limitation of liberty, which many freedom-loving Britons would resent and oppose to the last, even though it were consistent with the highest policy of preventive medicine.

DISTURBANCE OF THE PYLORIC MECHANISM.

THE control of the neuro-muscular mechanism of the alimentary canal is so complex, and the precise details are so little understood even by those who have concerned themselves more particularly with its study, that others may be forgiven for paying scant attention to a subject on which any hypotheses they might form would rest on so slender a basis of known facts. But in the British Medical Association Lecture published to-day at page 359 Professor John Fraser takes the general medical reader by the hand, so to speak, and leads him through such knowledge as we have about the distribution of the sympathetic and parasympathetic systems, and then brings forward evidence in support of the hypothesis that certain abdominal conditions of doubtful etiology, such as hypertrophic stenosis of the pylorus, Hirschsprung's disease, and the intussusceptions, are really due to a muscular hypertrophy produced by motor impulses beyond the control of the normal inhibitory mechanism.

Following this line of thought it may be profitable to draw attention to one example of disturbances of the neuro-muscular mechanism which, even if still wrapped in mystery so far as the method of its production is concerned, is yet of serious importance in the elucidation of otherwise obscure clinical problems. The controlling action of the pylorus has been the subject of much experimental work, and although certain elementary facts about it are fairly clear, they are perhaps by no means generally appreciated, and are often wholly misunderstood. The introduction of the stomach tube by Kussnaul as a clinical method of investigating disturbance of gastric function focused the attention of physicians more particularly on the secretory aspect of these problems, and for many years but little real attention was paid to any muscular derangement. With the advent of x-ray examination the position changed; a method was now available by which the movements could be seen and studied, and Cannon, in his classical work on the acid control of the pylorus, gave clear experimental evidence of factors operating at the pyloric sphincter. Since then increasing attention has been paid to the musculature of the alimentary canal, with a general tendency to ascribe particular importance to derangements in the neighbourhood of the sphincters.

With regard to the pyloric sphincter, Boldyreff proved conclusively by experimental methods that one of the chief functions of the pylorus was, not only to regulate the passage of chyme from the stomach to the

intestine, but also to permit the regurgitation of alkaline fluid from the duodenum into the stomach, and in this way to regulate the acidity of the gastric contents. Unfortunately the arrival of yet another method of clinical study of gastric function, in the shape of fractional test-meal examinations, directed attention once more to the secretory theories, largely owing to a lack of appreciation of the fundamental facts that Boldyreff had established, and a consequent misconception of the factors on which variations in the acid curves depended. Applying Boldyreff's observations to clinical problems, Dr. Charles Bolton has shown that the highly acid gastric contents which in former times were supposed to denote a dyspepsia dependent upon hypersecretion are in reality due to defective pyloric function, which does not permit adequate regurgitation of the alkaline duodenal fluid to neutralize the gastric contents; and conversely, that low gastric acidities are often due to an abnormally free regurgitation, and by no means necessarily denote a deficient secretion. Cases of true hypersecretion, or true achylia, are, indeed, comparatively rare, but cases of defective pyloric function, permitting on the one hand an excessively high and on the other an abnormally low gastric acidity, are extremely common.

We thus see that the estimation of the gastric acidity by the fractional method gives, as Dr. Bolton has insisted, no accurate picture of the gastric secretion; but it does give a very suggestive idea as to the vagaries of the neuro-muscular apparatus controlling the pyloric sphincter. The evidence obtained by test-meal examination is confirmed by that from x-ray observation, but both methods are open to serious objection when we come to apply them to clinical problems. In each case we are introducing into the stomach a bland non-irritating meal which cannot in any sense be expected to reproduce the same response to the very mixed diet to which patients are ordinarily accustomed. Still, so far as they go, both methods agree in suggesting that a defective pyloric mechanism is a fairly common event, and is indeed by no means incompatible with normal health. Moreover, they show quite clearly that the same defect may be present in a number of entirely dissimilar pathological conditions. A spasm or achalasia of the pylorus may be associated with a pyloric or duodenal ulcer, equally with these functional disturbances; an unduly free regurgitation may be allowed in cases of ulcer of the body, in carcinoma, or in functional disorder. At first sight this seems to suggest that the detection of such a defect in the harmonious working of the neuro-muscular mechanism can be of little value in the elucidation of clinical problems. But a more critical consideration will show that it may in reality provide the key to much that is puzzling in the wonderful variations of symptoms associated with gastric disorders; for the suggestion seems clear that, given an underlying defect in the pyloric mechanism, the local symptoms of any superimposed gastric disorder will depend in the main not so much on the gastric lesion itself as on the response of the pylorus thereto.

Full appreciation of disturbances of the neuro-muscular control of the pylorus affords also a comparatively simple explanation of those cases, to which Professor Fraser refers, in which lesions of the abdominal viscera far removed from the stomach give rise to symptoms indistinguishable from the symptoms of these gastric lesions, even though we are as yet far from understanding the actual nervous mechanism responsible for them.

THE MEDICAL PUNDITS.

ONE of the curious phenomena of our present-day social life—at any rate in the South of England—is the amount of space the newspapers give to medical pronouncements on everyday matters. Why do they do this? The explanation must be that their readers like it. And why do some of our eminent colleagues scatter these gems of wisdom at public and semi-public gatherings and in the course of interviews with reporters? It must be from a high sense of duty. They feel they have a message to deliver. In their hearts they hate publicity; but they know the truth about such things as rubber corsets, shingled hair, high heels, and cocktails, and (like brave fellows) they are determined to speak out for England's sake. The popular newspapers, we suppose, are no better than they should be; their public dotes on titbits and must be fed; and if highly decorative members of our profession are so obliging as to furnish "good copy," why not make the most of it with the aid of headlines and portraits? Thus lip service is paid to Hygeia, and a million blameless citizens are entertained at small cost, as they go to and fro in trams and trains. And the medical pundits, for their part, have also a double reward: the consciousness of duty done, and (deep in the subconscious) a feeling that it is not altogether a disadvantage to keep on good terms with the press in these censorious days.

Now, every reader of the *BRITISH MEDICAL JOURNAL* has not the time to read all that appears in the morning and evening newspapers; yet if oracular sayings about health are good for the public to hear, it surely follows that the medical profession ought to hear them too. It may well be that some of us, no less than our patients, need instruction on these matters. Here, then, are a few gleanings from the harvest of the past fortnight's *obiter dicta medica*.

On February 13th an audience in the East End of London was entreated by a physician not to let their daughters and nieces cultivate "that willowy figure," because it leads to digestive troubles and a greater risk of consumption. The craze, he said, won't last, and it does not make for a happy old age. But if it won't last, does it matter very much? Apparently, however, it does matter, because a no less eminent surgeon, in an interview granted next day to a reporter, declared that it is the weedy women of to-day who are producing the weedy young men. They cut their hair, shorten their skirts, and flatten their figures, so that it is at times difficult to tell a boy from a girl. We should have none of the diseases common to civilization (he added) if women were normal. How many of our readers, we wonder, have thought to matter out like that, and got to the core of the problem? Hard upon these tremendous maxims there appeared the report of a lecture given by a neurologist to an audience at the other end of London. The girl of the present day, he said, even when in her teens, has a freedom of action which is fraught with more than one danger. But these dangers—in the West End—do not, it seems, include the willowy figure. Here the trouble arises from restaurants, dances, night clubs, cinemas, cocktails, champagne, liqueurs, whiskies and sodas, tobacco, and drugs; in short, the modern girl "has become quite out of hand." What is the remedy? The neurologist, with his special opportunities, can and will help us: "Hygiene of body and mind are much needed in these days." The newspaper in which we saw this report gave it no more than three headlines, phrased (like the lecture) with commendable

restraint: "Girls' Cocktails and Drugs. Wrinkled Faces at Twenty. Doctor on Lack of Discipline." In a future issue, if this form of public education goes on, we may give our readers some more examples of how it is done.

CARBON DIOXIDE CONTROL OF ANAESTHESIA.

THE administration of an anaesthetic is not infrequently one of the most exacting experiences of general practice, and Professor Yandell Henderson has insisted, in a lecture published recently in our columns,¹ that ignorance of the physiology of anaesthesia and a crude administrative technique must be held jointly responsible for this. In the course of his lecture he emphasized particularly the value of carbon dioxide in controlling the subsequent discomforts and the danger of acidosis. Dr. J. S. Lundy has recently reported² the results of using carbon dioxide in almost the entire field of general surgery. In contrast with Professor Henderson, who mentioned that the percentage of carbon dioxide found most effective was as high as 25; Dr. Lundy believes that the right percentage varies for different patients and in different stages of the operation, but should in no case exceed 5. The anaesthetic is thus rendered safer and its administration easier. Dr. Lundy found that the special carbon dioxide-attachments for the ordinary gas apparatus did not prove satisfactory, and he has been using, therefore, a four-control modification of the results enumerated by Professor Henderson, and refers particularly to the value of increasing the ether absorption rate, diminishing the struggling and cyanosis, quickening the revival of the patient and his elimination of the anaesthetic, and improving the prognosis in bad cases. Dr. Lundy reports also that carbon dioxide may be added with advantage to a light anaesthetic mixture in obstetrical cases at the time when the child's head presses against the perineum and begins to dilate the external outlet; the mother's tendency to hold her breath and to bear down, in spite of all remonstrances, is thereby abolished. In dental anaesthesia also it has been found very useful in children, diminishing the struggling and cyanosis. The signs of overdose are said to be coughing, abdominal and thoracic movements, and holding the breath.

WILLIAM WITHERING, M.D., F.R.S.

IN the first number of the new series of the *Birmingham Medical Review* Dr. W. H. Wynn appropriately recounts the life-history of William Withering (1741-1799), who is the most notable of his predecessors on the physicians' side of the General Hospital, Birmingham. Withering came of an old Shropshire and medical family, for his father was in busy practice and his mother was a sister of Dr. Brooke Hector of Lichfield, a family with which Samuel Johnson was much in touch. William Withering went to Edinburgh to whose "affable disposition" and "modesty" he subsequently paid a tribute, took the M.D. in 1766. On one of his journeys to Edinburgh he made the acquaintance of Thomas Fowler (1736-1801), then an apothecary at York, who qualified later at Edinburgh in 1778, and, succeeding Withering at Stafford, published in 1786 his treatise "Medical Reports on the Effects of Arsenic in the Cure of Agues, remitting Fevers, and periodic Headaches," and with the help of Hughes, the apothecary there, compounded a substitute—liquor arsenicalis (Fowler's solution)—for the quack remedy then known as "Tasteless

¹ *BRITISH MEDICAL JOURNAL*, December 19th, 1925, p. 1170.
² *Journ. Amer. Med. Assoc.*, December 19th, 1925.

ague and fever drops." In 1795 Withering was consulted by letter by Fowler, who thought that he had angina pectoris, described by William Heberden the elder in 1768, but altered the diagnosis to spasmodic asthma. About 1766 Withering settled at Stafford, where he became sole physician to the hospital, which still has the Withering Samaritan Fund, and soon became popular for his musical talents and proficiency in private theatricals. Among his first patients was his future wife, whom after curing medically he continued to educate in literary and artistic taste, and it is said that his first researches on the British flora were the outcome of his anxiety to supply her with subjects to draw. Marriage in 1772 made his responsibilities greater, and three years later, in the hope of correspondingly increasing his income, he moved, on the advice of Dr. Erasmus Darwin, to Birmingham. At first he lived in a house previously occupied by Wyatt, the inventor of the first cotton-spinning machine, and also for a short time by Dr. Robert James, so well known for his fever powder, imitated by the *British Pharmacopoeia's* pulvis antimonialis. He at once became very active in chemical and physical work, published "A Botanical Arrangement of all the Vegetables growing in Great Britain, according to the System of the Celebrated Linnæus," and was elected a member of the famous Lunar Society, which included Joseph Priestley, James Watt, and Josiah Wedgwood. This hard work was followed by evidence of tuberculosis in 1776, the symptoms of which recurred in 1783, and in 1790 and 1791 caused attacks of pleurisy. The riots in July, 1791, when Joseph Priestley's house was burnt and his own threatened, had an evil influence on his health, and, resigning his hospital appointment in June, 1792, he went abroad; bearing his cross with fortitude, he fought the disease, which did not carry him off till October 6th, 1799. He was elected physician to the General Hospital in 1779; but the year before he investigated a severe epidemic of scarlet fever, and at first drew a distinction, which he afterwards abandoned, between scarlatina anginosa and angina gangraenosa; Dr. Wynn, however, considers that probably his first impression was correct, and that the ulcerated sore throat was what would now be called Vincent's angina. His work "An Account of the Fox-glove, and some of its Medical Uses: with practical remarks on Dropsy and other Diseases" (1785) was the result of ten years' careful observation of its administration; indeed, in 1776 his medical friends were using it mainly as a diuretic and for dropsy, though he recognized its influence on the heart. It is noteworthy that little improvement on his general directions for its use was made for a hundred years. Dr. Wynn rightly goes into Withering's work on digitalis in some detail, and further shows that he was a really great man as well as a distinguished physician and botanist. It is to be hoped that he will similarly describe the lives of other great Birmingham men, such as Joseph Hodgson (1788-1869) of Hodgson's disease, and John Ash, founder and first physician of the General Hospital, to whom he refers in this interesting and well written article.

PHYSIOTHERAPY CLINICS IN AMERICA.

IN an address to the Electro-Therapeutics Section of the Royal Society of Medicine on February 18th, Dr. E. P. Cumberbatch related his experiences of a tour in the United States and Canada, during which he visited seventeen cities, including six universities and more than forty hospitals and clinics. He found our colleagues across the Atlantic pursuing physiotherapy with great energy and resource, and he described the American practice in respect of four treatments—diathermy, sinusoidal currents, radiant heat or light, and ultra-violet radiation. Diathermy is

the most widely used treatment of this order, and the American apparatus differs much from that in use here. The spark-gaps attached to the diathermy machines in America are, it appears, all of the open type and multiple, six, eight, or ten spark-gaps being used. Some machines are without spark-gaps, and a three-plate thermionic valve is employed so that a current of sustained oscillations is produced. Excision of malignant growths is carried out in several clinics by a diathermic method which amounts to a form of surgical operation. The electrode is an ordinary thin steel needle, three or four inches long, fixed to a holder and attached to the terminal of an apparatus giving these sustained oscillations. When this needle is drawn across the tissues the tissues appear to "fly open before it," and coagulation is produced on each side to a depth of about 0.1 mm., so that lymphatic oozing and capillary bleeding are stopped. Dr. Cumberbatch saw this demonstrated at Baltimore by Dr. Howard Kelly, who called the instrument the "aigusector." It was stated that the tissues cut by this "aigusector" could heal by primary intention; a certain amount of shock, however, is not uncommon. In America diathermy is applied to a malignant growth at a much earlier stage than is customary here. It is also used extensively in the treatment of enlarged tonsils; under superficial anaesthesia the tonsils are fulgurated, but several applications are necessary, spaced by intervals of days, before treatment is completed. Haemorrhoids are very generally subjected to surgical diathermy, the treatment being by fulguration or, as the Americans prefer to call it, "desiccation." A further employment of diathermy is in the treatment of acute lobar pneumonia, and Dr. Cumberbatch was informed that the temperature begins to drop by lysis soon after the application. An apparatus widely used in the United States is a wave generator, originated by Dr. Morse of Boston, which gives a galvanic (direct) current, a sinusoidal current, and a sine wave or pulsating current, and each of these currents is made to surge—that is, to alternate rhythmically between the minimum and maximum many times a minute. With sinusoidal currents of higher frequencies than are customary here it is said to be possible to secure more even contraction of muscles between electrodes. Dr. Morse himself had used the current with success in enteroptosis with stagnation of the colon. Two kinds of lamps are used for radiant heat or light treatment, one giving a larger and the other a smaller proportion of heat. This method is used for the relief of deep-seated pain. For ultra-violet treatment the mercury vapour lamp is almost universally employed: Dr. Cumberbatch only saw one carbon arc in use. With regard to teaching in physiotherapy, many of the medical schools have courses, but these are optional except in the University of Pennsylvania, where Dr. Tait McKenzie, professor of physical education, takes the students through a compulsory course after they have completed their anatomy and physiology. Another point brought out in the address was that the practice of physiotherapy in America depends largely on the employment of "aides." The doctor in charge makes the examination and diagnosis and prescribes the treatment, which is undertaken by the "aide." Facilities for training these "aides" exist at many schools, but there is nothing in America to correspond with the diploma in medical radiology and electrology of Cambridge. Dr. Cumberbatch attended the fourth annual physiotherapy convention in Chicago, a gathering of 750 members. The curious thing about this successful convention was that it was organized entirely by a firm of manufacturers of electro-medical apparatus. The programme was left to a medical committee, and the firm obtruded itself only to the extent of putting a selection of its apparatus in an adjoining room. Dr. Cumberbatch ended with an amusing account of a

demonstration of the "Abrams box," by a gentleman who had come all the way from California to Montreal for the purpose. Following the address an American visitor, Dr. J. H. Kellogg, who for more than fifty years has been superintendent and surgeon of the Battle Creek Sanatorium at Michigan, remarked that America looked to England, and especially to London, for a lead in medical progress. This was his own seventh visit to learn what he could from his British colleagues. He described the great institution at Battle Creek, with its medical staff of fifty, and claimed that it was the first to inaugurate team work. He gave an account of the physiotherapeutic equipment, the diet, exercises, and general regimen, and mentioned the ban upon exciting foods, alcohol, and tobacco. Dr. A. E. Barclay, who also recently visited Battle Creek, while joining in its praises, spoke of the joy with which he stole out at night, to the most secluded quarter of the grounds, to indulge in the forbidden pipe.

RECENTLY DEVELOPED METHODS FOR MEASLES PROPHYLAXIS.

THE prevention and treatment of measles by injection of serum of convalescent cases is being tested at several centres in France, Germany, and America, and though the work is still in the experimental stage the results so far obtained sound promising. We have not heard of any similarly organized centre for the sero-prophylaxis of measles in this country, but Dr. W. S. C. Copeman has given a good account of the Continental methods in a recent article,¹ and supplemented this with some notes on personal experience during the epidemic of measles in Paris in the first half of 1925. Though the causative microbe in measles remains undiscovered, there is ample evidence to show that the serum or whole blood of persons who are either convalescent from, or who have in the past suffered from, measles has a definite value in the prophylaxis of this disease. If such protective serum be injected in sufficient dose during the first five or six days after infection it can produce a complete passive immunity which lasts for about one to two months, while if it be injected in small doses after the fifth day a modified form of the disease will result, leading to active immunity of uncertain duration, but which many observers consider to be permanent. In order to give the methods of sero-prophylaxis a satisfactory trial, centres have been established for collecting, preparing, testing, and storing the serum: to such centres institutions and general medical practitioners may apply for supplies. The measles donor from whom the blood is obtained should be an adult or a child over the age of 10, who must have had a typical and unmistakable attack of measles. He must be tested for freedom from tuberculosis, syphilis, and malaria, and observed for several days after the blood has been taken to make sure he was not in the invasion period of some disease due to a blood-borne virus. The blood should be allowed to coagulate at room temperature; later the serum can be aseptically decanted, tested for sterility, pooled with the serums from at least two other subjects, and placed in ampoules of 3 to 5 c.cm. ready for use. Such protective serum is employed on different occasions with different objects in view. If injected into a normal person passive immunity results which lasts about one month. If injected during the first five days of the incubation period of measles a complete passive immunity will be established and the patient will not develop measles. After the fifth or sixth day, however, no amount of injected serum will do more than modify the case. There are other ways in which the serum has been used—for instance, in some cases the serum has been injected into a healthy subject who has been later inoculated with infective material from a case of measles. By

this means it is claimed that an attenuated infection occurs which results in active immunity. A great defect in the methods described is the lack of any satisfactory means of standardizing the protective substances, and until this is devised it is unlikely that those methods will inspire much confidence. Still, they will be watched with considerable interest, and may develop from this experimental stage to provide a remedy for this very serious infection among children.

MISTAKEN IDENTITY.

UNDER this heading more than a year ago¹ we noticed Mr. Eric Watson's book on the notorious case of Adolf Beck, who was twice convicted and suffered more than five years' imprisonment from this cause. We then referred to the very unsatisfactory methods of police identifications, by which the accused person is paraded among a number of others, who may or may not resemble him in feature, stature, or dress. The average witness probably regards this test as a kind of "where to find the cat" puzzle, in which he assumes that the culprit is certainly present and he is expected to pick him out. It is to be feared that only too often he or she picks out the person who seems most to resemble the offender, without being really convinced of his identity. We pointed out the risk of mis carriage of justice in such cases as those of Beck and Stinnie Morrison, and urged that personal identification of this sort, unless supported by weighty evidence of another kind, ought not to be enough to secure a conviction. Recently Mr. Clifford Sully has reprinted with additions a paper on this subject which he contributed to *Hedrick* in 1912.² After giving various instances of illusions, which challenge the evidence of the senses and are familiar to every student of physiology, Mr. Sully goes on to analyse and discuss the mental processes which lead to identification. He suggests that this proceeding should form part of the trial, and that the would-be identifiers should be put upon oath, with the intention of impressing upon them the seriousness of the occasion. As things are now conducted it may happen, as he says, that the accused is really condemned by the identification before the trial in court has begun. If a witness picks out a man whom he thinks the most like his remembrance of the culprit, he is very apt to think that he has picked out the man remembered, and to say forthwith, "That is the man!" whereas, as Mr. Sully says, he is really recognizing because he picks out and not picking out because he recognizes. Before one of his trials Beck was identified by ten witnesses, although there were marked differences in personal detail between him and the culprit. But it is significant that six witnesses failed to identify him, and that one said that she was quite certain that he was *not* the man. Yet very little weight appears to be given to such important, although negative, evidence. The fact is that in this matter, as in many others, quality is of greater value than quantity, and in the Beck case it turned out that the evidence of the six witnesses who failed to identify was of more importance than that of the other ten. It is well known that individuals differ enormously as regards their susceptibility to suggestion, and perhaps even more so as to their quickness of perception and their visual memories. There is a parlour game in which the competitors are allowed to look for a short period at a number of miscellaneous articles spread out on a tray. At the end of the allotted period the tray is withdrawn, and the competitors are asked to make out a list of the articles they remember to have seen. A wide range of powers of visual memory will be thereby revealed in any company on which this experiment is tried. A more elaborate test (quoted by Mr. Sully) took place in Germany, where during the meeting of a scientific society

in carnival time a clown pursued by a negro with a revolver rushed into the hall. There was a struggle, a shot, and the couple rushed out again. Thereupon the president, who alone knew that the incident had been prearranged and photographed, requested every member to write a report of what had occurred. Of this select audience only one omitted from his report less than 20 per cent. of the characteristic events of the scene, and one-quarter of the reports contained 10 per cent. of imaginary occurrences. If men of scientific training fail thus, what is to be hoped of the average man or woman? In cases of identification of a prisoner or suspect it should be possible by a few simple tests such as are well known to anthropologists to estimate the relative value of each witness's evidence, by ascertaining his or her susceptibility to suggestion and powers of perception and memory, just as the credibility and character of a witness may be tested in open court. We are disposed to agree with Mr. Sully in his opinion that the process of identification should form part of the trial, although it probably could not be carried out in the actual court-room.

NEOPLASMS OF THE TESTICLE.

In a Hunterian Lecture delivered before the Royal College of Surgeons of England on February 12th, Mr. H. W. B. Cairns of the London Hospital gave an account of the nature, diagnosis, and treatment of various testicular new growths, paying particular attention to the teratomata. He pointed out that since the classic paper of Wilms in 1896 it had been generally recognized that the mixed tumours of the testicle were teratomata. Data had slowly accumulated to show that, with the single exception of the rare testicular "dermoid," the teratomata of the testicle were extremely malignant. The malignancy of these tumours had been held to be a carcinomatous or sarcomatous degeneration of a previously benign tumour, but the study of some ninety-five tumours of the testicle at the London Hospital had shown that this view was incorrect. Both primary tumour and metastases exhibited the same remarkable power of differentiating to form histologically benign tissues, exactly similar in structure to the tissues of the normal foetus. Thus the teratoma retained its biological characters in its metastases, and was, therefore, inherently malignant. Evidence of the foetal nature of teratomata of the testicle was afforded by the occasional discovery of chorionic elements in the tumours, and also by the observation of true hypertrophy of the breasts in some cases. Three cases were recorded in the literature in which such breast changes were noted, and three further cases were now added from the London Hospital. Considerable controversy had raged as to the nature of the common spheroidal-celled tumour of the testis, variously described as alveolar sarcoma, carcinoma, or séminome. In 1911 Ewing had claimed that this tumour was teratomatous, but his view had not been generally accepted either in this country or in France. The London Hospital cases, however, provided overwhelming evidence that the spheroidal-celled tumour belonged to the teratoma group. Cells morphologically identical with the spheroidal cells were found in great profusion in almost every teratoma of the testis, and tumours occurred which were, even to the naked eye, mixtures of teratoma and spheroidal-celled tumour. The exact position of the spheroidal-celled tumour in the teratoma group was not quite clear. Ewing had contended that the spheroidal-celled tumour was formed by overgrowth of one element of a pre-existing teratoma, but his view received no support from the present series of cases. On the contrary, the evidence from the London Hospital cases suggested that the cells of the spheroidal-celled tumour were totipotent, and that they arose in the seminiferous tubules. Professor Cairns thought that the London Hospital cases threw suggestive light on the much

discussed relation of injury to tumours of the testicle. It was highly probable that the part played by injury was not to initiate the neoplastic process, but rather to stimulate the more rapid growth of a pre-existing but hitherto unobserved tumour. Approximately one-third of the cases were cured by operation. The figures of the London Hospital cases, Mr. Cairns added, were slightly favourable to the radical operation as compared with the more simple operation of orchidectomy.

AMONG those recommended on February 18th for election to the Fellowship of the Royal Society were four members of the medical profession. Dr. Joseph Arthur Arkwright, assistant bacteriologist to the Lister Institute, has made a profound study of infectious diseases, in particular of typhus and trench fever, and of the serological classification of bacteria. Dr. Edwin John Butler has been director of the Imperial Bureau of Mycology at Kew since 1920, and before that held appointments under the Government of India. Lieut.-Colonel Samuel Rickard Christophers, C.I.E., was a member of the Malaria Commission of the Royal Society and the Colonial Office from 1898 to 1902, and has been working at the Central Research Institute in Kasauli. Dr. Hamilton Hartridge is a Fellow of King's College, Cambridge, lecturer in special senses and senior demonstrator of physiology in the University; during the war he was experimental officer at the Kingsnorth station of the Royal Air Force.

A FURTHER report on cancer of the breast, with special reference to its associated antecedent conditions, by Dr. Janet E. Lane-Clayton, has been issued this week by the Ministry of Health as No. 32 of its series of Reports on Public Health and Medical Subjects. Dr. Lane-Clayton's previous report, in which she presented a thorough review of the literature of this form of cancer in its relation to surgical treatment, was discussed in a leading article in our issue of October 4th, 1924 (p. 628). We shall consider her present findings and conclusions in an early issue.

WE much regret to announce the death, in Dublin on February 20th, of the Right Hon. Michael Francis Cox, M.D., LL.D., a former President of the Royal College of Physicians of Ireland and Chairman of Convocation in the National University of Ireland. We regret also to learn of the death of another distinguished member of the Irish medical profession, Mr. John Benjamin Story, honorary surgeon oculist to the King in Ireland, and a past President of the Royal College of Surgeons in Ireland and of the Ophthalmological Society of the United Kingdom. We hope to publish obituary notices shortly.

THE Executive Committee of the General Medical Council, at its meeting on February 22nd, had before it a request to call a special meeting of the Council to consider the application of Dr. F. W. Axham for the restoration of his name to the *Medical Register*. The Executive Committee decided against the proposed special meeting, and the application will accordingly come before the Council during its next session, which opens on Tuesday, June 1st. On January 14th, 1926, the Council of the Royal College of Surgeons of England considered Dr. Axham's application for restoration to membership, but did not see fit to rescind its resolution of July 13th, 1911, removing him from membership of the College. At a special meeting of the Royal College of Physicians of Edinburgh, held on January 19th, the suspension of Dr. Axham's licence, which had been imposed on May 7th, 1912, was removed. Dr. Axham obtained the M.R.C.S. diploma in 1861 and the L.R.C.P. Edin. in 1867. His name was erased from the *Medical Register* by direction of the General Medical Council on May 24th, 1911.

MORPHINE AND HEROIN ADDICTION.

DEPARTMENTAL COMMITTEE'S REPORT.

THE Ministry of Health issued at the close of last week the report¹ of the Departmental Committee on Morphine and Heroin Addiction, which was set up in September, 1924, by Mr. John Wheatley, when Minister of Health, with the following reference:

To consider and advise as to the circumstances, if any, in which the supply of morphine and heroin (including preparations containing morphine and heroin) to persons suffering from addiction to those drugs may be regarded as medically advisable, and as to the precautions which it is desirable that medical practitioners administering or prescribing morphine or heroin should adopt for the avoidance of abuse, and to suggest any administrative measures that seem expedient for securing observance of such precautions.

The chairman of the committee was Sir Humphry Rolleston, Bt., and the other members were Sir William Willcox, Dr. John W. Bone, Dr. R. W. Branthwaite, Dr. G. Matheson Cullen, Professor W. E. Dixon, F.R.S., Dr. John Fawcett, Dr. Adam Fulton, and Dr. J. Smith Whitaker. It will thus be seen that the committee was wholly medical in constitution. The secretaries, whose services are acknowledged at the end of the report, were Dr. E. W. Adams and Mr. R. H. Crooke, of the Ministry of Health.

In the following February, acting upon a suggestion by the committee, Mr. Wheatley's successor, Mr. Neville Chamberlain, extended its terms of reference as follows:

To consider and advise whether it is expedient that any or all preparations which contain morphine or heroin of a percentage lower than that specified in the Dangerous Drugs Acts should be brought within the provisions of the Acts and Regulations and, if so, under what conditions.

The committee held twenty-three meetings and took the oral evidence of thirty-five witnesses, of whom twenty-four were medical men. Four witnesses represented the British Medical Association, three the Pharmaceutical Society of Great Britain, and several others gave evidence on behalf of wholesale and retail pharmacists. The medical evidence included that by consulting physicians of wide experience in the treatment of nervous and mental disorders, by medical men having special experience in the treatment of addiction, by medical officers of prisons, and by representative general practitioners from various parts of the country. Further information regarding the prevalence of addiction was obtained through the regional medical officers of the Ministry of Health from general practitioners of wide experience.

The matters referred to the committee for its consideration fell under four main heads:

- (i) The circumstances, if any, in which it may be medically advisable to administer morphine or heroin to a person known to be suffering from addiction to these drugs;
- (ii) The precautions which medical practitioners ought to adopt in administering these drugs, both generally and with particular reference to persons suffering from such addiction;
- (iii) The administrative measures, if any, which we might think it advisable to recommend to secure due observance of such precautions;
- (iv) The advisability or otherwise of bringing within the scope of the Dangerous Drugs Acts preparations of morphine or heroin containing percentages of the drugs lower than are at present included.

The report is divided into six sections; the first contains some preliminary observations, which include a summary of the provisions of the Dangerous Drugs Acts and the Regulations made thereunder, and of the present system of administration, followed by a statement of certain difficulties said to have been experienced in the course of administration.

Under these Acts, it will be remembered, possession of the specified drugs is restricted to persons licensed or authorized for such purposes. A registered medical practi-

tioner is authorized to be in possession of the drugs, and to supply them, "so far only as is necessary for the practice of his profession." All persons authorized to supply the drugs, including medical practitioners who dispense medicines for their patients, are required to keep records of drugs purchased and issued, but this requirement does not apply to drugs administered by doctors personally, or under their immediate supervision. Practitioners who do not dispense, and therefore do not supply drugs otherwise than by way of personal administration, are not at present required to keep a record even of their purchases. Records kept by medical practitioners are inspected on behalf of the Home Office by the regional medical staff of the Ministry of Health in England and Wales, and by the corresponding medical staff of the Board of Health in Scotland.

Cases are from time to time brought to the notice of the Home Office in which exceptionally large quantities of these drugs have been supplied to particular practitioners, or in which individual patients have received unusually large quantities on medical prescriptions. The results of inquiries into cases of this kind are indicated in the report, also the difficulties that at present lie in the way of appropriate action in order to secure better observance of the law. Whether the law has been broken turns in such cases usually on whether the drugs were supplied for purposes of medical treatment only.

Prolonged Administration.

In considering this matter, the question arose whether it was medically necessary that in any circumstances morphine or heroin should be supplied continuously for long periods to persons not suffering from any organic disease for the relief of which such drugs were essential. This in turn raised the question, to which the committee addressed itself with much pains, whether abrupt withdrawal of the drugs is feasible, more particularly under the conditions of ordinary private practice. Careful collation of the literature led to the conclusion that the practicability of the method of sudden deprivation depends on the possibility of inducing patients to enter an institution. In view of the risk of intense suffering and even fatal collapse, this method calls for close supervision under expert judgement and skill and trained nursing; moreover, there is a relative dearth of appropriate institutional accommodation in Great Britain as compared with the United States, where some authorities favour sudden withdrawal under proper precautions.

Assuming abrupt withdrawal to be impracticable, even if thought advisable, in a large proportion of the cases of addiction in this country, the question arose whether this would justify the practice of administering "maintenance" doses of morphine or heroin for however long periods. Inquiry showed that some physicians of great experience hold the view that there are two classes of persons from whom—at all events under the conditions of ordinary private practice—the drugs could not be entirely withdrawn. In one class the attempt at complete withdrawal produces severe distress and even risk of life; in the other, experience shows that a certain minimum dose is necessary to enable the patient to lead an ordinary and relatively normal life, and that if deprived of this non-progressive dose he becomes incapable of work. The fact that this view is held by some eminent authorities made it difficult to base action on the assumption that continuous administration of non-diminishing doses, for however long a period, is necessarily inconsistent with bona-fide medical treatment.

Another question studied by the committee was the cases in which a doctor supplies or orders dangerous drugs for persons whom he sees infrequently, or for persons whom he sees for the first time and respecting whom he has no communication from the patient's ordinary medical adviser. A further question, even more difficult, was the case of doctors who are themselves addicts. Owing to the authority possessed by medical practitioners to obtain the drugs, they do not encounter the same obstacles in getting excessive supplies as an ordinary member of the community, who can only get them from a doctor or on a prescription. These and the other matters mentioned above were those in regard to which the Home Office sought the committee's advice.

Medical Aspects of Addiction.

Section II summarizes the results of the committee's inquiries into certain medical aspects of the problem of addiction—its nature, causation, and prognosis. The term "addict" is defined as follows:

"A person who, not requiring the continued use of a drug for the relief of the symptoms of organic disease, has acquired, as a result of repeated administration, an overpowering desire for its continuance, and in whom withdrawal of the drug leads to definite symptoms of mental or physical distress or disorder."

In regard to the prevalence of addiction the evidence all tended in the same direction, and its collective effect supports very strongly the conclusion that in this country addiction to morphine or heroin is rare. There was also a general concurrence of testimony to the effect that addiction has diminished in recent years, most of the witnesses attributing this to the operation of the Dangerous Drugs Acts, which have made it difficult to obtain these drugs otherwise than from or through medical men. On the one hand, those who were already addicts when the restrictions came into operation have been driven to placing themselves under medical care or overcoming their infirmity for themselves; on the other hand, new addicts are not being created as they were under former conditions. From all this the committee points the moral that "the prevention and control of addiction must now rest mainly in the hands of the medical profession, since, in the main, it is through them alone that the drug can be obtained."

Of the two forms of addiction morphine in any of its forms is much the commoner, but the addiction produced by heroin is the more disastrous in its physical and mental results, and more difficult to cure. In the case of morphine the evidence showed that hypodermic injection is much more likely than other methods of administration to lead to addiction and that addiction so arising is harder to cure. The nature and causation of morphine and heroin addiction are, however, so closely associated that the committee considered them together. All the evidence tended to show that in the great majority of cases the drug, whether morphine or heroin, is taken, not for the purpose of obtaining positive pleasure, but to relieve a morbid and overpowering craving. "The only immediate cause of addiction is the use of the drug for a sufficient time to produce the constitutional condition that is manifested in the overpowering craving and the occurrence of withdrawal symptoms when use is discontinued." The following specific events were regarded by medical witnesses as having led to the development of addiction in different cases, and the committee discusses them separately. These are: (1) use of the drugs in medical treatment; (2) self-treatment for the relief of chronic or recurrent painful or distressing physical conditions, or for the relief of emotional distress; (3) example or influence of others; (4) curiosity, bravado, and search for pleasurable experience.

The committee next discusses the three methods of treatment—abrupt withdrawal, rapid withdrawal, and gradual withdrawal—and their relative value. The opinion of the witnesses who appeared before it was for the most part strongly in favour of the gradual withdrawal method. Treatment, after-care, and prognosis are then reviewed. Section III considers the circumstances in which it might be medically advisable to administer morphine and heroin to persons known to be suffering from addiction to these drugs, and Section IV the precautions to be observed in their administration. Section V discusses the administrative proposals to which the Home Office invited attention, and others which witnesses suggested or which occurred to the committee during its deliberations. In Section VI the committee, in accordance with its supplementary reference, considers certain preparations at present excluded from the scope of the Dangerous Drugs Acts.

The whole report is a document of great medical interest and should be read by all practitioners whose work brings them in contact with these distressing cases of drug addiction. It has also sociological aspects which deserve close study. The general tenor of the report will be gathered from the committee's carefully summarized conclusions and recommendations, which are printed together at the end. In view of their importance we reproduce them substantially in the committee's own words.

CONCLUSIONS AND RECOMMENDATIONS.

The first group of these relates to medical questions, some of which have been briefly mentioned above.

Prevalence of Addiction.—Addiction to morphine or heroin is rare in this country, and has diminished in recent years. Cases are proportionately more frequent in the great urban centres, among persons who handle these drugs for professional or business reasons, and among those specially liable to nervous and mental strain. Addiction is more readily produced by heroin than by morphine, and addiction to heroin is more difficult to cure. Facility of access is an important factor in the production of addiction.

Nature and Causation of Addiction.—With few exceptions addiction to morphine and heroin should be regarded as a manifestation of a morbid state, and not as a mere form of vicious indulgence. The immediate cause of addiction is the use of a drug for a period sufficient to produce the constitutional condition manifested by "craving," and the occurrence of withdrawal symptoms when the drug is discontinued. Addiction is more readily induced in some persons than in others, the most important predisposing cause being an inherent mental or nervous instability. There is evidence, however, that addiction may be induced by injudicious use of the drug in a person apparently free from any manifestation of nervous or mental instability, and, conversely, that due care in administration may avert this result even in the unstable. Other predisposing causes are chronic pain or distress, insomnia, overwork, and anxiety. In a considerable proportion of cases the circumstance which has immediately led to addiction has been the previous use of the drug in medical treatment. Other circumstances noted have been self-treatment for relief of pain, recourse to drugs in emotional distress, influence of other addicts, and indulgence for the sake of curiosity or the experience of pleasurable sensations. Cases of addiction originating in use of the drugs otherwise than under medical orders must be expected in future to diminish.

Treatment and After-Care.—While authorities differ as to the relative value of abrupt or rapid withdrawal of the drug and gradual withdrawal in the cure of addiction, the committee draws the following conclusions from the evidence:

(a) Abrupt or rapid withdrawal cannot be carried out safely except under conditions which afford complete control of the patient's access to the drugs, and close and continuous observation of the effects of the treatment, such as are usually to be found only in special institutions or nursing homes.

(b) Gradual withdrawal will, therefore, with rare exceptions, be the only practical method under the ordinary conditions of private practice, and the only one applicable to patients who cannot afford or are, for other reasons, unwilling to enter institutions or nursing homes.

(c) Abrupt withdrawal may be advisable for young otherwise healthy adults in whom the addiction is of recent date, and so far has entailed moderate doses only; in other cases gradual withdrawal is on the whole to be preferred even under institutional conditions.

(d) Abrupt withdrawal is specially dangerous in old or seriously debilitated persons, patients with well marked organic disease, and those taking exceptionally large doses.

(e) Institutional treatment, while with rare exceptions indispensable for the abrupt method, also affords the best hope of cure by the gradual method, and patients should always, if possible, be induced to undergo treatment in an institution or nursing home.

(f) Success in enabling any patient, by either method, to become (for the time being) independent of the drug must be regarded as the completion of the first stage of treatment only. For permanent cure a prolonged period of after-care is necessary in order to educate the patient's will-power and to change his mental outlook. For this part of the treatment information should be obtained by a close investigation, during the first stage, of the conditions which brought about the addiction, and if a factor, such as pain or insomnia, contributed to the causation, every effort must be made to remove or cure this before the patient is released from observation. Attention must also be paid to the possibility of improvement in the patient's social conditions.

Prognosis.—Estimates of the proportion of complete cures of cases treated vary from 15 or 20 per cent. to 60 or 70 per cent., the highest percentages being claimed by practitioners adopting the abrupt method, who had carried this out in institutions or homes.

Legitimate Administration to Addicts.

There are two groups of persons suffering from addiction to whom administration of morphine or heroin may be regarded as legitimate medical treatment—namely, those who are undergoing treatment for cure of the addiction by the gradual withdrawal method; and persons for whom, after every effort

has been made for the cure of the addiction, the drug cannot be completely withdrawn, either because complete withdrawal produces serious symptoms which cannot be satisfactorily treated under the ordinary conditions of private practice, or because the patient, while capable of leading a useful and fairly normal life so long as he takes a certain non-progressive quantity, usually small, ceases to be able to do so when the regular allowance is withdrawn.

Precautions in Administration to Addicts.—Under treatment by the gradual withdrawal method the addict should, if possible, be induced to enter a suitable institution or nursing home. If this is not feasible, the practitioner must attempt to cure the condition by a steady judicious reduction of the dose, with a view to ultimate complete withdrawal. The patient should be kept under close observation by the practitioner, should be in the care of a capable and efficient nurse, and under sufficient control to preclude any possibility of obtaining supplies of the drug other than those medically ordered. If the practitioner finds that he is losing the requisite control, or the course of the case indicates a probability that complete cure cannot be effected, he will be well advised to obtain a second opinion before assuming the responsibility of indefinitely prolonged administration. Where indefinitely prolonged administration appears to be needed, the main object must be to keep the supply of the drug within the limits of what is necessary. The practitioner should be satisfied as to urgency before ordering or supplying morphine or heroin to a patient concerning whom he has no previous knowledge, and careful inquiries should be made from the patient, at the beginning, as to the previous or concurrent sources of supply. The minimum dose necessary should be administered and (unless organic disease is present) repetition withheld until the practitioner has obtained details of the case from the previous medical attendant.

Precautions in the use of Morphine and Heroin in Ordinary Medical Practice.

The committee advises that regard should be paid at all stages of the case to the possibility of substituting for morphine or heroin, either temporarily or permanently, drugs which do not involve the risk of addiction. If morphine or heroin is essential, care should be taken not to give larger or more frequent doses than are strictly requisite to achieve the object in view. Cases requiring daily administration should be seen as often as the doctor feels to be necessary, and the amount ordered or supplied should not exceed that required until the patient is seen again. Discretion to nurses as to administration of the drug should be strictly limited by prescription, and any change made in the treatment should be stated in writing. The patient should not be informed either of the name or dose of the drug administered. Whenever other methods of administration will produce the desired effect, hypodermic injections should be avoided. In no circumstances should the patient be allowed to administer the drug to himself hypodermically. The drug should be discontinued immediately it is no longer needed. Should a craving result, close supervision and appropriate treatment must be maintained until the medical attendant is satisfied that the patient has been rendered independent of the drug.

Valuable results, the committee believes, might accrue from the judicious instruction of medical students in the precautions necessary to avoid the production of addiction to morphine and certain other drugs. Medical men already in practice should welcome the issue of some authoritative memorandum affording guidance upon this difficult and important subject, and the issue of such a memorandum is therefore recommended.

Administrative Measures.

Withdrawal of Authorization.—The present position under which a doctor's authorization to possess and supply the drugs can only be withdrawn after a conviction under the Dangerous Drugs Acts is not satisfactory, either administratively or from the point of view of the medical profession. Accordingly, the committee recommends that the Home Secretary should have power to withdraw the authorization without conviction in the courts, if so advised by a suitably constituted medical tribunal. Tribunals should be constituted whose function it would be to consider whether or not there were sufficient medical grounds for the administration of the drugs by the doctor concerned, either to a patient or to himself, and they should advise the Home Secretary whether the doctor's right to be in possession, to administer, and to supply the drugs should be withdrawn. There should be separate tribunals for England and Wales, and for Scotland, and each should be composed of one member nominated by the General Medical Council, one by the appropriate College of Physicians, and one by the British Medical Association, with a legal assessor.

Control of Prescribing.—The committee advises that any doubt as to the power of the Home Secretary under the present Regulations to control the prescribing of dangerous drugs should be removed by a suitable amendment to the Regulations. The Home Secretary should also have power, after the conviction of a doctor in the courts for an offence under these Acts, or on the advice of a medical tribunal, to withdraw the practitioner's authorization to prescribe dangerous drugs.

Second Opinions.—In the interests of patients and of practitioners themselves, it is held to be desirable that the practice should be generally followed of obtaining second opinions before undertaking the responsibility of continuing to administer drugs in cases in which there is no medical reason for doing so, other than treatment of the addiction. This applies also to the patient who needs indefinite administration of the drug for the purpose of enabling him to lead a normal and useful life. The Regulations should not, however, require a practitioner to obtain a second opinion, but it should be regarded as a professional obligation, such as is already generally recognized in respect of the decision to carry out certain other forms of treatment.

Record of Purchases by Non-dispensing Doctors.—In the committee's opinion doctors who do not dispense should be required to keep a simple record of their purchases of dangerous drugs, and this could most easily be done if the invoices of purchases were pasted in a book.

Preparations at Present Excluded from the Acts.

With the possible exception of chlorodyne, there is little, if any, abuse or danger of addiction arising from any preparations at present excluded from the scope of the Dangerous Drugs Acts. As regards chlorodyne there was considerable difference of opinion, but it appeared that its free sale as a common domestic remedy has given, and does give, rise to certain risks of addiction. In the committee's view there is no present need, for the prevention of addiction, to lower the limit of morphine content now fixed by the Acts. The position as regards chlorodyne would, it suggests, be met if no preparation were allowed to be sold under the name of "chlorodyne" which contained more than 0.1 per cent. of morphine.

Globa et Vetera.

GLISSON AS AN ORTHOPAEDIC SURGEON.*

In the last century it was by many thought odd that the senior physician to one of the great general hospitals should practise orthopaedic surgery, but two hundred years ago it would not probably have excited criticism, for medicine and surgery were not then completely divorced. Sir D'Arcy Power has told us how surgeons as late as the seventeenth century struggled in vain to free themselves from the control of the physicians. And only a few weeks ago a hospital physician, writing in the *BRITISH MEDICAL JOURNAL* (January 2nd, p. 36), claimed "that except in cases of trauma no laparotomy should be performed save with the sanction of the physician." But nearly a century before Glisson's great treatise on rickets appeared, Ambroise Paré had shown that there was at least one surgeon who needed no physician to tell him what to do.

Glisson describes surgical apparatus and treatment just as a surgeon might have done and without any hint that he employed a surgeon to carry out his directions. Although I am only dealing with one aspect of his activity, I may fitly remind you of some facts of his life, referring you for more details to the writings of Sir Norman Moore in the *St. Bartholomew's Hospital Reports* and the *Dictionary of National Biography*.

He was born in Dorsetshire in 1597, became M.D. Cantab. in 1634, and F.R.C.P. Lond. in 1635. He was Censor in 1656 and President in 1667, 1668, and 1669. He was Regius Professor of Physic at Cambridge for more than forty years. He died, aged 80, in 1677. His published works are: "*De Rachitide sive morbo puerili Tractatus*"

* Abstract of a paper read before the History of Medicine Section of the Royal Society of Medicine, February 17th, 1926, by E. Muirhead Little, F.R.C.S.

(1650), "Anatomia Hepatis" (1654), in which Glisson's capsule is described, "Tractatus de Natura Substantiae energeticae, seu de vita naturae ejusque tribus primis facultatibus" (1672), and "Tractatus de Ventriculo et Intestinis" (1677).

The "Treatise of the Rickets," as Phil. Armin, its translator in 1651, called it, was ostensibly the work of a number of physicians, of whom three, Drs. Glisson, Bate, and Regemorter, were finally responsible for its publication, which was licensed by the censors. In the preface, however, it is stated that Dr. Glisson found out the essence of the disease, and that they "committed the first stuff of the whole work to be woven by him alone," and that it "should presently undergo the examination and judgement of the rest, as if it had been fashioned by their hands."

The first mention of rickets is to be found in the Bills of Mortality of the City of London for 1634 (Granger 5.2.3. Bills of Mortality 1602-1666. Library of the Corporation of the City of London), in which year there were about fourteen deaths attributed to the disease. In 1659 the number had increased to 476. Obviously the diagnosis was very much haphazard.

Glisson's description of the naked-eye morbid anatomy is wonderfully complete. Scarcely one of the usual symptoms of the disease escaped his notice. But he was a thorough-going Galenist, and a large part of the book consists in speculations about elements, humours, constitutions, and vital, animal, and natural spirits. He maintains that it is not a cold, but a moist distemper, and "this disease consisteth in the stupefaction of the spirits." He gives quite a luscious account of the loves of vital and natural spirits. As for internal remedies, they were copious, and include such things as worm-oil, woodlice, frog's and raven's livers, stone-horse-dung in a clyster, and such-like.

The surgical pathology and treatment is more reasonable. With the help of a number of woodcuts he explains his theory of the production of deformity by overgrowth of

FIG. 1.

FIG. 2.

FIG. 3.

one side or part of a bone. (Figs. 1 and 2.) He says: "We compare the bones therefore, in which this crookedness useth to happen, to a Pillar." Then he goes on to show how if you add material between the elements of the pillar on one side only it becomes bent as in the second figure. If you add still more and in more places it becomes a bow. (Fig. 3.)

As regards rachitic knee deformities, he argues rightly that the tibia is more in fault than the femur, and shows this by woodcuts (Fig. 4), of which he says:

"In the joynt of the knee A.B., that part of the Shank bone B. [tibia in the original] in the two first figures, is higher than the other part of the same appendance, whereupon the bone of the thigh C. is inwardly bowed, and so likewise is the shin bone D., but the joynt A.B. is thrust somewhat outwardly. But in the two

FIG. 4.

FIG. 5.

last figures all the contrary things may be observed. The Joynt A.B. is inwardly, because that part of the shin bone A. is higher than the other part of it B. Whereupon it must needs lift up the inner and lower top of the Thigh-bone, so that the Thigh-bone will be bent outwardly, and the Joynt inwardly."

This fact was only rediscovered some forty years ago, and is undoubtedly correct in most cases. He extols the value of rubbing, and says that it increases nutrition and therefore should be confined to the concave side of the deformity, thus anticipating the modern theory of massage. He denied, however, that the bones are abnormally soft in rickets, and therefore did not recognize the influence of the body weight and of muscular contraction and tone acting upon too soft bones. A number of woodcuts are devoted to demonstration of the production of chest deformities; as, for instance, in Fig. 5, in which A is the sternum and B the spinal column. He argues that if the part behind the line CD is unaltered and the part in front overgrows it must push the sternum forward as in the lower figure, thus producing a pigeon breast.

In Chapter XXIX he comes to surgical matters. He thought that there might be something in the treatment by scarification of the veins in the hollow of the ear (which proceeding seems to have been popular), by its effect through the fifth cranial nerve on the spinal marrow. Ligatures are recommended "to retard the overslippery return of the blood in those parts." Does not this foreshadow Bier's hyperaemic treatment? As regards appliances, he recommends buttoned boots stiffened with splints or pieces of whalebone on the convex side. In two woodcuts a jointed splint for the knee is represented in considerable detail, according to which I have had one made. But that the thigh and leg part are much too short, these would be

FIG. 6.

quite efficient. As he gives no measurements of length it seems likely that the drawings have been modified to suit the small size of the page. (Fig. 6.) There are two joints, which allow flexion and extension at A and B—surely a peculiar and unnecessary arrangement. No doubt bandages were used to fix these splints to the limbs. Modern surgeons would place them on the concave side, whereas Glisson preferred the convex, guided, no doubt, by his theory of unequal growth and of the advantage of pressure on the overgrown part. There must, however, have been considerable risk of pressure sores. Among external remedies for spinal deformity he recommends recumbency with pillows under the prominence. He here cautions the reader against allowing patients to stand or walk too soon: "for walking rather confirmeth than cureth the bended joynts."

Then he describes what has since been widely known as Glisson's sling, by means of which the patient is hung up by the head and shoulders and to be swung to and fro. This, he says, is a pleasure to the spectators and "rather a pleasure than a trouble to the child." I have myself slung up many children, but none of them seemed to enjoy the process. The object of this suspension was "to restore the crooked bones, to erect the bended joynts and to lengthen the short stature of the body. Moreover it exciteth the vital heat and withal allureth a plentiful distribution of the Nourishment to the external and first affected part." Besides these measures frictions and abdominal massage of a quite vigorous sort are advocated. Plasters to the loins and sacrum are recommended, the shape of which seems to have been important, for a figure is given to show that which is preferred.

I hope that I have said enough to justify my title and to show that there are at least grounds for the claim that the President of the Royal College of Physicians in 1667, 1668, and 1669 was an orthopaedic surgeon as well as a physician. Indeed, I think that he is as much entitled to be called the father of orthopaedic surgery as Dr. Andry of Paris, although he did not invent a name for this branch of surgery.

I have pleasure in acknowledging my debt to Dr. Arnold Chaplin, who has kindly lent a copy of the first edition of the "Treatise" from the Library of the Royal College of Physicians, and also to Mr. H. E. Powell, the librarian of this society, for much valuable help in the preparation of this paper.

STATUS LYMPHATICUS.

COMMITTEE FOR COLLECTIVE INVESTIGATION.

IN view of the importance of the question of "status lymphaticus," particularly in regard to the exact part, if any, which it plays in the causation of sudden death, the Medical Research Council and the Pathological Society of Great Britain and Ireland are desirous of collecting information on the weights and measurements of the thymus gland on a large scale.

The investigation was originally begun just before the war, but first the war and afterwards the death of the secretary and organizer, Professor Emrys Roberts of Cardiff, seriously militated against the success of the scheme. A certain amount of material was collected and a short interim report was published in the *Journal of Pathology and Bacteriology* in April, 1925. The number of records, however, was far too small to permit of any authoritative conclusions, and the present scheme aims at the collection of a much larger mass of material.

The special objects of the investigation at present are:

1. To establish, by means of a large series of weights and measurements, the standards of weight for age, and the proportion to body weight of the normal thymus at all ages.

2. To investigate closely the precise cause of death in persons dying suddenly from unexplained and trivial causes, where the only apparent abnormality is the presence of a large thymus.

To promote these objects the following committee has been formed:

Sir Frederick Andrewes, St. Bartholomew's Hospital.
Professor J. S. Dunn, University of Manchester.
Professor J. S. C. Douglas, University of Sheffield.
Professor Leonard Findlay, University of Glasgow.
Professor E. E. Glynn, University of Liverpool.
Professor E. H. Kettle, University of Wales, Cardiff.
Professor Robert Muir, University of Glasgow.
Dr. A. F. B. Shaw, College of Medicine, Newcastle-on-Tyne.
Professor J. Lorrain Smith, University of Edinburgh.
Professor M. J. Stewart, University of Leeds.
Professor J. H. Teacher, University of Glasgow.
Professor H. M. Turnbull, London Hospital.
Professor G. Haswell Wilson, University of Birmingham.
Dr. Matthew Young, Medical Research Council.
Dr. W. Howel Evans, University of Liverpool (*Secretary*).

Part of the scheme evolved by this committee is the appointment of a number of investigators in large centres to collect detailed records. But, in addition, the committee earnestly invites all other pathologists and practitioners who perform *post-mortem* examinations to co-operate. The categories of cases in which information is especially desired are:

(a) Cases of sudden death in apparently healthy persons of any age, including deaths from accident.

(b) All cases of death in persons of 15 years or over who have an apparently glandular thymus.

For this purpose record cards have been prepared, and the secretary will send a supply to those who apply for them. Realizing that many workers have not the time or facilities for such full investigation as will be carried out by the special investigators, two types of record cards have been prepared: *Record Card I* provides space for full details, *Record Card II* provides space for brief details. The details mentioned on the first card include the body weight and length, the weight of the kidneys and spleen, the dimensions and weight of the thymus, the proportions of the fatty and glandular tissue in it, and its anatomical relation to the trachea. Details of the faucial and lingual tonsils; the cervical, coeliac, and mesenteric glands; the Peyer's patches, and solitary follicles of the intestine; and the diameter of the Malpighian bodies of the spleen are also desired. The state of nutrition, the cause of death, and any evidence of feminism in males are to be recorded. The second card contains headings for the length and weight of the body, the thymus weight, cause of death, and major pathological conditions. On the reverse of both cards further investigations are suggested in cases in which the cause of death is not obvious at the *post-mortem* examination. These include blood culture from the cerebral sinuses for evidence of septicaemia, microscopic sections

of the left ventricle wall, lung, suprarenals, parathyroids, brain, spinal cord, kidneys, liver, spleen, and the bones for rickets, with sections of the costo-chondral junction if rickets is not demonstrable elsewhere.

The committee earnestly hopes that a large number of workers will send for a supply of these cards and return such information as may be possible to it.

Applications should be made to the Secretary of the Committee, Dr. Howel Evans, Pathological Department, the University, Liverpool.

Ireland.

MEDICAL REGISTRATION IN THE FREE STATE.

THE position of medical registration in the Irish Free State was referred to in our issue of January 23rd (p. 156). Mr. R. C. B. Maunsell, President of the Royal College of Surgeons, at the annual meeting of the Incorporated Orthopaedic Hospital of Ireland, in the course of his address said that two years ago a committee was formed to bring about the amalgamation of at least five of the city hospitals. The initial cost of the scheme appeared to be prohibitive, but after negotiations the committee had almost concluded arrangements for a gift of a large sum of money from the Rockefeller Foundation, when the Rockefeller authorities broke off negotiations until such time as the vexed question of medical registration should be settled satisfactorily. What had happened about medical registration? asked Mr. Maunsell. On December 21st last the committee of medical men who were negotiating with the Government were received most courteously, cordially, and sympathetically by President Cosgrave and Mr. McGilligan. "Two very important things happened at that conference. We were informed that a bill would be introduced extending the existing system for six months or more, in order to give time for the discussion of a permanent arrangement. This has been done, and, as you are all aware, the present system can be continued until the end of the year. Suggestions for a permanent arrangement, which should be satisfactory to both sides, were submitted by the committee. These suggestions were received sympathetically, and three medical men were chosen as a subcommittee, at the request of President Cosgrave, to discuss details with the Ministers and lawyers who would frame the bill. Since the date of that conference, December 21st, 1925, these three medical men have not been consulted in any way about this vitally important matter. Meanwhile, our medical students continue to stray to other seats of learning, and in all probability the Rockefeller money will be applied to public health matters in China or some other enlightened country. We are deeply grateful to the Government for renewing the old system and so preventing chaos, but I for one would like the details of the permanent arrangement thrashed out, as promised by the President. No medical man will deny intervals of sleep to hard-worked Ministers and lawyers, but to sleep, apparently continuously, from December 21st to February 17th is perilously near to sleeping sickness." Mr. Maunsell added that he had raised his voice that day in the hope that it might be wafted across Merriem Street, into the Local Government Board office.

HOSPITAL PATIENT AND DOCTOR: ACTION FOR ASSAULT.

A recent action in the Dublin High Court, in which one of the most distinguished and most highly respected of Irish physicians was sued for assault by a hospital patient, has aroused great interest, both in professional and other circles.

The plaintiff alleged that on October 3rd, 1924, when she was a patient in Monk-town Hospital suffering from severe spinal injury and fracture, the defendant, Dr. T. Gillman Moorhead (now Regius Professor of Physic in Dublin University), entered the private ward in which she was and, despite her protests, assaulted her, whereby she was seriously injured in her health. She claimed £1,000 damages. The defence traversed the alleged cause of action, and the defendant said the acts complained of by the plaintiff were performed by him in the course of

a proper medical examination, which was carried out by the authority of the plaintiff and with her leave and consent. Counsel for the plaintiff said she joined a V.A.D. in 1914, and worked in King George V Hospital in Dublin. In June, 1916, she met with an accident in that hospital whilst attending a wounded soldier, when her back was crushed against the ironwork of the bed. Plaintiff was attended by many doctors in Dublin from time to time, and ultimately obtained a pension of £90 from the War Office. In September, 1924, she came under the care of Dr. de Courcy Wheeler, and entered the Monkstown Hospital. The plaintiff, having giving evidence in support of her claim, stated, in cross-examination on commission, that before she joined a V.A.D. she had been a militant suffragette, and had undergone imprisonment for her exertions on behalf of that cause. She admitted that she brought an action in 1913 against the Irish Women's Franchise League to restrain them from expelling her, and that the action was dismissed by the Master of the Rolls. In 1923 she brought an unsuccessful action against the Young Women's Christian Association, because, as she alleged, they unlocked her box and took things out of it. Three doctors were subpoenaed on behalf of the plaintiff, but declined to give evidence, as in each case the subpoena was only accompanied by a "viaticum" of half a crown. Mr. Justice Hanna remarked that it was extraordinary that proper arrangements had not been made for the attendance of medical witnesses, instead of tendering half-crown fees in court, and added that, having regard to the position of medical witnesses, the fee of ten guineas was reasonable remuneration. A professional man was entitled to, and could insist upon being paid, compensation for loss of time, and he therefore considered the fee demanded was reasonable having regard to the fees paid to other professional people in Dublin. Dr. T. G. Moorhead, the defendant, in the course of his examination, said he was consulting physician to the Monkstown Hospital. He was asked by Dr. Wheeler to see the plaintiff, to whom he mentioned that Dr. Wheeler had told him about her symptoms, and he would commence by examining her reflexes, which he did, and the plaintiff made no remonstrance. The matron had prepared her for examination, covering her with a towel in the usual way. Dr. Wheeler was in the room all the time, and the plaintiff co-operated with the defendant during his examination. Dr. Moorhead stated that he heard that the plaintiff, after a few days, left the hospital because her sister had objected to his examination. Dr. Moorhead added that it was his deliberate opinion that the plaintiff was suffering from hysteria, and that there was no evidence of any injury at any time to her back; he had examined an x-ray photograph of the plaintiff's spinal column, and believed the spine to be absolutely normal. Dr. K. E. L. G. Gunn, surgeon to the Adelaide Hospital, stated in his evidence that the plaintiff was admitted to the Adelaide Hospital as a patient from the Ministry of Pensions; he examined her on different occasions, but could find no trace of any disease or abnormality of her spinal column. He came to the conclusion that she was a case of hysteria, and that she showed no desire to get better. As to the statement of the plaintiff that they had "broken her back" in the Adelaide Hospital, Dr. Gunn said that was the first he had heard of it. Drs. Purser, Beckett, Hardman, and Harvey also gave evidence on behalf of the defendant, and stated that the x-ray photographs which were taken by them showed no abnormality or injury to the spine of the plaintiff. In his charge to the jury, Mr. Justice Hanna first stated the law as regards the rights of patients and medical men in an examination. The legal basis, said his lordship, was the consent of the patient. When a patient called in a doctor there was either an implied or an expressed consent that the doctor should be entitled to do all such acts as he considered reasonably necessary in his opinion, having regard to the state of medical knowledge and his own experience, to discharge his duty in making a diagnosis. But it was always subject to this—that, if he proposed to do any act dangerous or painful to the patient, he should give the patient such information as would enable the patient to give or withhold consent. The plaintiff's contention was

that, without her leave, Dr. Moorhead was forced upon her, scandalously and needlessly exposed her, hit her on the back with a stethoscope, injuring her, and dragged her up and down the room. That brought them to the consideration of the characters and personality of the two persons. The plaintiff should not be decided against because she was a suffragette, had been in prison, and had brought several unsuccessful actions. But, said his lordship, these facts were relevant in considering the type of woman that she was; whether she would be scrupulous about bringing unfounded charges, or, on the other hand, prone to do so. Dr. Moorhead should not be believed merely because he was an eminent doctor, but his counsel were entitled to say that the plaintiff's contention would not be true unless not only Dr. Moorhead, but also Dr. Wheeler and the matron, had all gone mad on that morning, or had conspired to adopt "shock tactics" in examining the plaintiff. The jury, after an absence of ten minutes, brought in a verdict that no assault had been committed. His lordship entered judgement for the defendant, with costs.

The *Irish Times*, in a leading article, congratulated Dr. Moorhead on the happy issue of his extremely unpleasant ordeal, and went on to say that the public should realize the serious risks to which doctors were exposed in the exercise of their profession. They had virtually no protection against frivolous or malicious charges, and Dr. Moorhead's case was typical of many others in which medical men of the highest personal and professional integrity had been compelled to defend their reputations in public. The relations between a doctor and his patients were so intimate that he might be said to deliver his good name into their hands at every visit. Fortunately Dr. Moorhead had had unimpeachable witnesses of his actions on the occasion which led to the charge against him; but every day he and his colleagues examined patients in privacy. It was therefore essential that the medical profession should be governed by a body which exercised the strictest control over the professional attainments and moral characters of its members. Many criticisms (the article added) had been made recently against the General Medical Council; but its very conservatism in the matter of professional qualifications and etiquette saved the public from undesirable doctors. To this expression of opinion by a responsible lay newspaper we may add, in the name of the medical profession, an expression of sympathy with Professor Moorhead and of congratulation on the successful outcome of his ordeal.

Scotland.

EDINBURGH UNIVERSITY: NEW SURGICAL DEPARTMENT.
The buildings and equipment in connexion with the chair of surgery at Edinburgh University, provided out of funds supplied by the Rockefeller Foundation, are now practically completed. Some two years ago a grant was given in aid of research work, of which part was set aside as a supplement of the salary of the university chair of surgery now held by Professor Wilkie, in order that this department might be conducted on a modified full-time basis; part was devoted to equipment of the surgical department for research purposes, and part still remains to be expended in connexion with a clinical research laboratory in the Royal Infirmary. Students of a past generation will remember the surgical theatre in the university as one of great height provided with a gallery. This has now been remodelled, and the theatre has been divided horizontally by the introduction of a new floor. There is ample accommodation for the students, whose numbers are now considerably diminished below those of the period succeeding the war, and by the abolition of the gallery the students are brought nearer the lecturer. The lower half of the old theatre has been arranged as a series of practical rooms, in which microscopic demonstrations can be given and operative surgery be taught to small groups of students. One of the rooms has been fitted up as a museum of surgical pathology. An electric lift

communicates with the lecture theatre above, and facilitates the conveyance of material required for lectures. The new research department is situated in an adjoining building, which was previously set apart for women students, and this building is connected with the lecture theatre by a passage. It has been partitioned into a series of rooms for experimental research work. Adjoining this are an office for the laboratory assistant, a small common room for the research workers, the professor's room, secretary's room, and other accommodation. Each research worker's bench is provided with electric light, electric power, hot and cold water vacuum suction, and taps from which air under pressure is drawn. The operating theatres have double glass roofs, of which the inner one is provided with pipes to spray the glass and carry away dust; the rooms are equipped with a dust-clearing steam arrangement by which, before an operation, the room is filled with steam, which condenses and carries down the suspended dust. The floors are laid with rubber so that they can be easily flushed. Adjoining the operating room is an x-ray room, with the most recent equipment for taking photographs during an operation. A side room is set apart for anaesthetizing animals before they are operated upon, and there are also recovery rooms with heating pipes and electrically heated mats. The animal house adjoining the research house has been enlarged by the addition of another story.

GLASGOW WESTERN INFIRMARY.

The fifty-first annual meeting of the subscribers to the Western Infirmary of Glasgow was held on February 17th, when the Lord Provost, Sir M. W. Montgomery, presided. He congratulated the directors on the finance report, which showed that the income was greater than in the previous year. The David Elder Infirmary at Govan, to be opened this year, would form a very valuable adjunct to the Western Infirmary, and be a means of reducing the long waiting-list of patients. The report submitted to the meeting showed that the total revenue of £91,981, including legacies, exceeded the total expenditure of £91,510, thus enabling the managers to carry to capital account £471; the ordinary expenditure, however, still exceeded the ordinary income by £6,956. The number of patients treated in the wards during the past year was 10,287, and of out-patients 33,214. The average daily number of in-patients had been 556, and the average cost per patient per day was 7s. 8d. The total number of persons on the staff of the infirmary was 514. The David Elder Infirmary at Govan, subject to a satisfactory adjustment of details between the managers of the infirmary and the trustees, was to be administered by the managers of the Western Infirmary, and the buildings would have 42 beds for patients, with possibility of extensions from time to time as funds were provided by the public, without interference with the present structure. The report of the Lady Hozier Convalescent Home, Lanark, showed that the treatment of convalescent patients from the Western Infirmary continued as formerly; 446 patients had been admitted during the course of last year, and, on an average, retained for three weeks.

GLASGOW ROYAL CANCER HOSPITAL.

A reception was held on February 17th in connexion with the installation of a modern electrotherapeutic department in the Glasgow Royal Cancer Hospital. The new addition has been built of brick and has been heavily protected so as to minimize the danger of the rays used in the deep Erlangen treatment to which one room is devoted. A second room is used for taking skiagrams and for barium meals, and a third room is equipped with two Westminster arc lamps for ultra-violet ray therapy. At the junction of the first two rooms is a room for an operator, heavily protected with lead, its windows opening into the treatment room being constructed of specially prepared glass, with protective power equal to 8 mm. of lead. A portable x-ray apparatus has been provided for use in the wards in the case of a patient who cannot be moved. Sir George Beatson, surgeon to the hospital, announced that the directors were now in a position to capitalize the sum of £20,000 to provide an income for research work. It was hoped that one gram of radium might be obtained before long.

EDINBURGH EYE INFIRMARY.

At the annual meeting of the Eye, Ear, and Throat Infirmary of Edinburgh Mr. J. P. Watson, honorary secretary and treasurer, submitted the report for 1925, which showed that the number of eye patients treated as out-patients was 3,838, while the ear, nose, and throat out-patients numbered 1,633. In the wards 297 patients had been accommodated, and there had been 637 operations. The ordinary income was £1,023, and the ordinary expenditure £866, leaving a credit balance of £157. The chairman, in moving the adoption of the report, said the institution was a notable example of the success of the voluntary principle in connexion with hospital finance.

INDUSTRIAL HEALTH.

The first annual report of the Industrial Health Education Council was presented on February 10th at a meeting of the council in Edinburgh; Lord Salvesen, president of the council, took the chair. In the latter half of 1924 an intensive programme had been planned and active efforts made to obtain the goodwill and support of workers' organizations. The Scottish Trades Union Congress Council had approved the Education Council's policy, and had circularized its branches in favour of the work. The educational programme began on January 22nd, 1925, and the workers' organizations had taken full advantage of the health talks which were offered, doctors giving their services gratuitously. Occupational sicknesses and diseases, the care of the teeth, food, and nutrition had been dealt with. In the spring and autumn of 1925, 74 health talks had been given, and the number arranged during the first three months of 1926 is 57, making in all 131 for Scotland. The council had given attention to the extension of the work in England, and meetings had been held with the Miners' Union in Northumberland and with the Miners' Association in Durham County, both of which bodies were taking steps to secure grants from the Miners' Welfare Fund to cover programmes in these counties. It was expected that Cumberland and South and West Yorkshire would also join. It was intended later to create executives in the Midlands, London, the West of England and Wales. Much encouragement in this work had been given to the council by the Ministry of Health. The expenses for meetings for miners had been met out of a grant of £400 by the Miners' Welfare Fund; other grants had been received, such as £500 from the Carnegie Trust, £100 from the Dental Board, and £105 from the Prudential Insurance Company.

At a meeting of the Edinburgh Chamber of Commerce and Manufactures on February 10th Sir Thomas Oliver of Newcastle-on-Tyne delivered an address on health problems and industrial amelioration. With regard to the eight-hour day, the lecturer said there were trades where it might be too short and trades where it might be too long, and it should be recognized that if work was carried to the extent of fatigue the best possible was not obtained from the workers. Work produced under the influence of fatigue was costly. Efficiency, however, was not a question entirely of the number of hours spent in a factory. It had been found in the North of England that the coal miners who had hobbies were, as a rule, far better workers than those who lounged about in the village street. It was believed that a working man starting at the age of 20 had the prospect of an average duration of life of 42 years—that is, he would probably reach the age of 62. But in the non-industrial classes the average longevity was eight years greater. The difference was not altogether a question of occupation. Food was an important consideration, for the wives of many working men did not make the best of the money available. The working man was also exposed to risks of accident, which were two and a half times greater than those of men in the non-industrial classes. In addition to this, there was an increased liability to certain diseases, and cancer was cited as a possible example of industrial disease. In the aniline dye works in Switzerland the workers were liable to contract cancer in the bladder, apparently owing to the dye being absorbed into the body and excreted into the bladder, where it caused the disease. As an example of what preventive medicine had done, the lecturer said that

when white phosphorus was used for matches many of the workers were attacked by disease. A substitute for this material was found which had no harmful influence, and there were then no further cases of the disease. As another example, he instanced the good results achieved by the use of aniline dye instead of arsenic in the manufacture of wallpaper, so that the number of cases of disease due to arsenic had been reduced from 358 in 1900 to 22 in 1923. Sir Thomas Oliver also spoke of the value of periodic medical examination, and concluded with an appeal for support for the Industrial Health Education Council.

CENTRAL MIDWIVES BOARD FOR SCOTLAND.

The examination of the Board, held simultaneously in Edinburgh, Glasgow, Dundee, and Aberdeen, has just concluded with the following results. Out of 136 candidates who entered for the examination 118 passed. Of the successful candidates, 29 were trained at the Royal Maternity Hospital, Edinburgh, 28 at the Royal Maternity Hospital, Glasgow, 7 at the Maternity Hospital, Aberdeen, 12 at the Maternity Hospital, Dundee, 18 at the Queen Victoria Jubilee Institute, Edinburgh, and the remainder at other recognized institutions in various parts of Scotland.

HERRING CURING IN SCOTLAND.

The Home Secretary has issued the draft of an Order proposed to apply to all factories and workshops in Scotland in which the various processes of curing herrings are carried on. The terms of the Order follow approximately the conclusions reached by a conference held between representatives of the Home Office and the Scottish Fish Curers' Association at the end of 1923, and require the provision of cleansing facilities for employees, the maintenance of a first-aid box or cupboard on the factory premises, and the establishment of a first-aid dressing station. It is interesting to note that a Scottish M.P. has this week spoken of the herring as "the backbone of Scotland's economic life."

England and Wales.

WELSH NATIONAL SCHOOL OF MEDICINE.

THE building of the new Institute of Preventive Medicine, which is only one of the generous benefactions of Sir William James Thomas to the Welsh National School of Medicine, makes good progress, and, it is confidently hoped, will be ready for occupation in the autumn. The ground floor is to be given over to the city and county laboratories, and Dr. E. L. Collis, Mansel Talbot professor of preventive medicine, and his staff, will occupy the first floor. It is proposed that the second floor shall be lent to the department of pathology and bacteriology for the time being, since the pathological block at the Cardiff Royal Infirmary is adapted only for routine work. Similar hospitality is to be offered to the department of tuberculosis on the top floor, which also contains the lecture theatre and animal houses of the institute.

The laboratories given by the Rockefeller Trust to the medical unit of the school are shortly to be erected, the final plans for the building and equipment being now under consideration. Indeed, nothing impedes the progress of this national medical school but the delay in ratifying the decisions of the Privy Council, the Royal Commission, and the University of Wales to make it a separate school of the university. Even the strongest opponents of the scheme, such as Principal Trow of Cardiff College, seem to have accepted, though not with a very good grace, the fact that separation must come. According to the reports of a recent meeting of the College Court of Governors, the point at issue between the University of Wales and its recalcitrant college is the future of the two departments of anatomy and physiology. The university—very properly, in our opinion—considers that a separate medical school means a complete school, including all the subjects in the curriculum. It is at the point between physics, chemistry, and biology, now definitely regarded everywhere as pre-medical studies, that the logical division must come. While

all must admire the sturdy spirit which refuses to recognize defeat and fights a losing battle to the last trench, there comes a time when mere stubbornness ceases to be a virtue. By its reactionary policy Cardiff College is impeding the progress which it cannot itself bring about; indeed, its action has already resulted in serious financial loss to the school. It is to be hoped that the college will be public-spirited enough to acknowledge this, and that no further hindrance will be put in the way of the development on national lines of the only national medical school in the United Kingdom.

THE MINISTER OF HEALTH ON VOLUNTARY HOSPITALS.

The Middlesex Hospital annexe, in Cleveland Street, 250 yards away from the main hospital, opened on February 23rd by Mr. Neville Chamberlain, Minister of Health. The annexe was formerly a workhouse infirmary, but has been derelict for some time, and £40,000 has been spent on reconditioning it for use during the rebuilding of the hospital itself. About a hundred patients formerly occupying the condemned wards have been moved into these new quarters, so that the empty block is now ready for the housebreakers as soon as the funds justify a start. For the rebuilding of the Middlesex half a million had to be raised, and rather more than half this sum is in hand. Prince Arthur of Connaught, chairman of the hospital, who presided over the ceremony, stated that the acquirement of this new building would not only ensure during the reconstruction of the hospital the maintenance of the full number of beds and of the hospital's services to the public as a treatment centre and a centre for medical education and research, but would afterwards remain, with some further structural alterations, as an ideal out-patient department—superior, he thought, to any other in London in floor space and in other respects. Mr. Chamberlain reminded the company that the old block of the Middlesex, built in the middle of the eighteenth century, was quite literally "falling down," but in due course the new hospital would rise, phoenix-like, from the ashes of the old. During the period of rebuilding, the simplest, easiest, and certainly the cheapest course would have been to accept no new patients, so that the number of beds would have been gradually reduced and the wards closed. But the board regarded the Middlesex as a necessary unit in the great voluntary system of London, and with courage and wisdom acquired the annexe to serve as temporary wards and eventually, when no longer needed for that purpose, to be a worthy out-patient department. An out-patient department might not seem as interesting or important as an in-patient department, but it represented the preventive side of a hospital's work, for there the physicians and surgeons saw the beginnings of disease and saved many patients from having to go into the wards. The opening of this building (the Minister continued) was a striking testimony to the vitality of the long-threatened but apparently unconquerable voluntary system. The voluntary hospitals of this country were unique in the world. They discharged three great functions: the provision of treatment for disease and accidents, the training of future practitioners (and it was significant that every teaching hospital, without exception, was on the voluntary principle), and the prosecution of research. Although research was now recognized and endowed by the State, and the great universities took their share in its development, the voluntary hospitals were the pioneers and were still carrying it on. Admittedly the voluntary system had its defects and gaps, and some would urge that the hospitals should be turned over to the State, and that use should be made of the boundless resources of the national exchequer. Whether those resources were in fact boundless the forthcoming budget would show. To his mind the destruction of the voluntary hospitals would be a disaster of the first magnitude, not on financial grounds alone. The nation for more than one reason could not afford to dispense with the voluntary sacrifice which the hospitals represented.

"It may be (Mr. Chamberlain said) that some day we shall succeed in so developing our health services as to come nearer to the ideal to which, I think, we all ought to look—to a plan under which there will be no unnecessary duplication, no waste,

no overlapping, and yet which shall offer to every citizen not merely the highest professional skill, but the use of all that wonderful apparatus and equipment which modern science has put at our disposal. Even to get an approximation to such an ideal means that we have got to co-ordinate every agency which is now working for the prevention and cure of disease. It may be necessary to ask our voluntary institutions to yield up something of the complete independence they enjoy to-day, but I feel convinced of this, that the changes must be so contrived as not to impair those great qualities which have made our voluntary hospitals the pride of this country—their individuality, their elasticity, and the personal sympathy and devotion which have characterized them ever since they have been in existence.”

PUBLIC EDUCATION IN HEALTH.

It is gratifying to learn that the people of this country are now not only willing to read public health literature provided for them by the Ministry of Health, but that their appetite grows by what it feeds on—they not merely accept instruction, they demand it. In July, 1924, the Ministry issued a memorandum by Sir George Newman on *Public Education in Health*, and now, only a year and a half afterwards, “this memorandum is reprinted to meet the exceptional demand for it.”¹ As was indicated in a full notice of the first edition,² the pamphlet is only thirty-five pages long; but in that brief space the author succeeds in presenting a remarkably comprehensive survey of the whole subject with which he deals. It is now brought up to date by including reference to the new Public Health Act of 1925, which fully empowers local authorities to undertake health education by the publication of information, the delivery of lectures, the display of pictures, etc. The price, as was the case in the original issue, is only sixpence, and we venture to suggest that not only should public health officials take an interest in its wide circulation, but that busy practitioners, besides reading it for themselves, should, when opportunity offers, bring it under the notice both of friends and of patients.

THE OPTICAL CONVENTION: LONDON, APRIL, 1926.

A programme of business has been issued for the Optical Convention which is to be held in London, at the Imperial College of Science and Technology, from April 12th to 17th. Two previous meetings of the kind have been held in London—one in 1905 and the other in 1912, under the presidencies respectively of Sir Richard Glazebrook and the late Professor Silvanus P. Thompson. Both were extremely successful, as the bulky volumes of their proceedings bear witness, but much molten glass has passed through the crucible since the second of these occasions. Progress has been made in optical theory, in the many sciences which make use of optical methods, and, most markedly perhaps, in the manufacture of optical elements and instruments. The British optical industry has made remarkable strides, a position of national independence has been reached with regard to optical materials, and the instruments now turned out from the benches of this country make it possible to say that most of the physical research which is proceeding in any part of the world is being aided by optical devices from British laboratories and workshops. All these circumstances make the time fully ripe for another convention which should be a means of bringing together various separated researches, and of acquainting those engaged in optical manufacture with the specific requirements of the users of optical instruments. The president of the convention is Sir Frank Dyson, the Astronomer Royal, and there are about sixty vice-presidents, including Sir Oliver Lodge, Sir Ernest Rutherford, and Sir William Bragg, together with the presidents of many scientific and technological bodies. The medical men whose names figure in the list of vice-presidents are Sir John Herbert Parsons, president of the Ophthalmological Society of the United Kingdom, Sir StClair Thomson, president of the Royal Society of Medicine, Sir Charles Sherrington, lately president of the Royal Society, Dr. James A. Murray, president of the Royal Microscopical Society, and Sir Ronald Ross. We understand that a very large number of papers have been

promised already, covering the subjects of optical theory, optical history and education, and the various applications of optics, from astronomy to microscopy, and from spectacle manufacture to aerial surveying. These papers and the discussions upon them will be embodied later in a volume of proceedings. An exhibition has also been arranged in three sections—one to illustrate research, a second to comprise objects of historical interest and the reproduction of famous experiments, and the third to be a commercial exhibit of British manufacturing firms. If the experience of the previous conventions is repeated, the catalogue of this exhibition, in spite of its commercial character, should prove quite a valuable work of reference for some time to come, giving as it will an adequate report on the condition of the British optical industry and full specifications of the various optical appliances shown. From this exhibition or even from its catalogue one may expect to gather for the first time in a comprehensive way what really has been done in British optics, partly under the stimulus of war, during the fourteen years since the last convention. So far as ophthalmic progress is concerned, this has gone much deeper than the mere provision of more ingenious and comfortable glasses and of frames more pleasing in appearance, and in ophthalmology, from the point of view of instrumentation alone, new fields have been opened out with the introduction, for instance, of the slit-lamp and the corneal microscope. The slit-lamp, although it had actually been invented just before the last convention, was not known to ophthalmologists generally until long afterwards. The subscription for membership of the convention is 15s. or £1 11s. 6d., the latter sum to include a copy of the proceedings, and the offices of the secretary are at 1, Lowther Gardens, Exhibition Road, London, S.W.7.

MANCHESTER POST-GRADUATE COURSE.

The Manchester Royal Infirmary post-graduate courses for the second half of the year 1925-26 will take the same form as in the previous year. On Tuesday afternoons, at 4.15, free lectures will be given each week from March 2nd until May 18th, with the exception of April 16th. The subjects dealt with during March include the diagnosis of nephritis, criminal abortion, haemorrhage about the menopause, atypical forms of acute appendicitis, and ectopic pregnancy. On Friday afternoons at the same time free demonstrations will be given on clinical cases and methods in the wards, special departments, and the laboratory. These demonstrations will be continued until May 21st, with the exceptions of April 2nd and 9th. Although there has been no co-ordination hitherto between the courses of the various Manchester hospitals since the war, it is hoped that before long some central scheme of training may be started, to take the form perhaps of a definite post-graduate school.

JOINT TUBERCULOSIS MEETING. AT CAMBRIDGE.

A combined meeting of the Tuberculosis Society and the Society of Superintendents of Tuberculosis Institutions will be held in Cambridge from March 25th to 27th inclusive. On the first day lectures will be given by Dr. James Crockett, medical superintendent of consumption sanatoriums in Scotland, on ultra-violet rays and tuberculosis, and by Dr. G. Marshall, assistant physician to the tuberculosis department at Guy's Hospital, on tuberculosis and pregnancy. A discussion on catarrhopyogenic and tuberculous infection of the lower respiratory tract will be introduced on the second day by Sir Humphry Rolleston, Bt., and Sir StClair Thomson will lecture on the indications, technique, and results of the galvano-cautery treatment of laryngeal tuberculosis. Professor Edgar Collis will speak on industrial fatigue in connexion with tuberculosis, and Professor Lyle Cummins will discuss sanocrysin, with special reference to the clinical point of view, technique, and selection of patients. On the last day a demonstration of apparatus for inducing artificial pneumothorax will be opened by Dr. H. de Carle Woodcock. A limited number of rooms are available at St. Catharine's College for those attending the meeting. Further information may be obtained from the joint

¹ *Public Education in Health*. A Memorandum addressed to the Minister of Health by Sir George Newman, K.C.B., M.D., F.R.C.P. Revised 1925. London: H.M. Stationery Office, or through any bookseller. 6d. net.

² BRITISH MEDICAL JOURNAL, vol. II, 1924, p. 580.

honorary secretaries, Dr. F. J. C. Blackmore, the Tuberculosis Dispensary, Plumstead, S.E.18, and Dr. J. R. Dingley, Darvell Hall Sanatorium, Robertsbridge, Sussex.

L.C.C. PART-TIME MEDICAL OFFICERS.

The public health department of the London County Council has hitherto employed forty-four part-time medical officers on yearly engagements, fifteen of whom have been employed for six half-days a week and twenty-nine for three half-days. The appointments of these officers expire on March 31st. Four of them are over 60 years of age, and it is not proposed to renew their appointments, and four others do not offer themselves for reappointment. The appointments of the remaining thirty-six officers, all of whom have rendered efficient service, are to be renewed for a further period of one year, and nine new appointments are being made. With these appointments the part-time medical staff will consist of twenty men and twenty-five women doctors, fourteen being employed for six half-days a week and thirty-one for three half-days. The salary for six half-days a week is £360 a year inclusive, and for three half-days £180 a year. The department has also twenty-nine full-time assistant medical officers.

Correspondence.

OPERATIVE TREATMENT OF PERFORATED GASTRIC AND DUODENAL ULCER.

SIR,—I have hesitated to enter into the discussion on the treatment of acute perforating ulcers of the duodenum and stomach, because I consider that it is useless to argue for or against gastro-enterostomy without a searching inquiry into the end-results.

It was my intention to await a period of two years after completing my first hundred cases before committing anything to print, but as I have already operated on over one hundred cases with only four deaths perhaps I may be excused for recording the general impression which I have formed.

Being assistant surgeon to two sets of wards (90 beds), I have to perform between twenty and thirty operations for perforations of the stomach and duodenum every year. The four deaths which I have had occurred before the first hundred series of cases was completed, so that my operative mortality rate is 4 per cent. for that series. As yet there are no deaths in the second series. Three of the four patients who died came from the country and travelled long distances. The other case had pulmonary and abdominal tubercle, and although he had been going about he died three months afterwards while still under my care. In each of the deaths a full *post-mortem* examination was performed. Only four of the perforations were gastric; the others were all beyond the pylorus. There was one case of recurrent duodenal perforation.

On twelve occasions at least the perforation was diagnosed as a case of acute appendicitis. The local treatment varied, but was either (1) simple suture, (2) excision of the indurated area with scissors and suture of the mucous membrane separately from the sero-muscular layer, or (3) cauterization of the indurated area, and in some cases so widely as to allow the mucous membrane to be thoroughly freed. In one case I burned right through the pylorus and did a pyloroplasty.

The infolding sutures are Lembert's, introduced transversely to the long axis of the duodenum, taking a good grip of the bowel wall and beginning distally, and working successively towards the pylorus. All four sutures are inserted before tying is commenced, and then omentum is sutured over all.

Fortunately, all the cases on which I did a gastro-enterostomy recovered. Comparing them with those of "local suture" only, I can definitely say that the cases with a gastro-enterostomy made a better immediate recovery from the actual operation, and I always felt happier about them. On the other hand, some seventy odd consecutive "local suture" cases recovered from this operation, so is there much danger, then, in not doing a gastro-enterostomy?

A gastro-enterostomy does lengthen the operation, but is this additional risk of time worth the more rapid immediate recovery? I cannot say. I am happier about the case where I have been able to do a gastro-enterostomy, but if I am in any doubt I do not do a gastro-enterostomy.

Now, to take the patient three months to a year after operation: I have a bigger percentage of cases returning with ulcer symptoms when a gastro-enterostomy has been performed. The cauterized cases without a gastro-enterostomy are a long way ahead of all the others. The ulcer, as it were, has been completely removed, and two sterilized edges are sewn together and infolded. Why need one do an additional and unphysiological operation in such cases?

These are questions which cannot be answered without careful scrutiny of end-results of many series of cases. My two chiefs will complete reviews of my end-results, so that the question of any bias cannot arise. But there is one point on which I have formed a definite opinion: I consider it practically impossible to narrow the duodenum in juxtapyloric ulcers. As long as the lumen of the duodenum is as big as the pyloric lumen there can be no obstruction. The pylorus itself limits the amount of infolding which can be produced, and a too tightly tied suture very soon cuts out.—I am, etc.,

Dundee, Feb. 18th.

JOHN TAYLOR, Ch.M.

THE STATISTICAL STUDY OF CANCER.

SIR,—Two questions have been raised, one of only personal, the other of general interest.

With regard to the former, I still think that a reader of Dr. Cramer's lecture, having no independent knowledge of the facts, might have inferred that the League of Nations Committee paid no attention to any statistics save those of cancer of the breast and uterus in England and Wales and Holland, an inference unjust to the statisticians concerned. I did not suppose that Dr. Cramer intended to misrepresent the position, and am sure that the point has now been made clear. The other question is of much more importance, and I must ask your permission to discuss it because, in my opinion, Dr. Cramer, in his letter of February 16th (p. 346), draws an incorrect particular conclusion from a general principle which is not only sound but of great importance.

The general principle—if I may be allowed to restate it in my own words—is this. No statistical investigation of cancer conducted, as it were, *in vacuo* will really advance our knowledge of etiology. It is true that the great majority of the "proofs" that cancer is "caused" by intestinal stasis, by eating meat, by the use of common salt, and so on, through the whole gamut of theories which so grievously waste the time of busy men, are rendered worthless by patent violations of the canons of statistical inference. But I believe it is also true that even a well trained statistician who acts on the principle that all he needs, in addition to his statistical equipment, is the stock of vague ideas respecting cancer possessed by, say, the average medical man without special laboratory experience, will not achieve anything of value. One reason is this. Incomplete as is our statistical literature of cancer, it is absolutely very large. If all the statisticians of the world were to set about testing the associations between variables which a loose general theorizing might suggest to be possibly relevant, they would be all dead before they had made any serious impression upon the data. Attention must, therefore, be concentrated upon associations which special researches have indicated as likely to be of importance, and the decision as to which come within this category is not wholly, not even mainly, a statistical question. The role of the statistician is to test, on the data available to him, hypotheses which, in his quality of technical statistician, he has not originated. He has, of course, like other men, the right to frame hypotheses, but his technical knowledge does not give them any special value.

So far Dr. Cramer and I are in complete agreement. Where we part company is in the particular application of the principle. Dr. Cramer said in his lecture, and virtually reiterates, that if statisticians had grasped the importance of the experimental evidence that the development of cancer in one organ inhibits its independent develop-

ment in another organ, they would not have overlooked a "very curious fact." Now what is this "very curious fact"? As I said before, the direct logical inference from the experimental work would be that the concurrence of cancer of two primary sites in the lifetime of an individual should be much rarer than would, on the average, be the case if the two events were independent. But this is a "fact" which statisticians cannot possibly overlook because they are not in the possession of any data adequate to reveal it. One cannot overlook the existence of the most curious phenomena on the dark side of the moon. If we had data of a large number of persons, hundreds of thousands, kept under skilled medical observation from puberty to death, we could solve the problem. We have no such data. Official statistics provide us with more or less accurate specifications of the causes of death. With the help of these we can calculate, more or less accurately; the probability that a person aged x will be certified to have died of cancer of the uterus or other form of cancer, and we can do no more. Suppose a woman, aged 40, had been successfully operated upon for cancer of the breast, and at the age of 75 developed, and died of, a cancer of the rectum. I see no reason why the certifying practitioner should make any reference to a condition which he might deem to have had neither directly nor indirectly any relation to the cause of death. We have, in a word, no reason to suppose that death certificates are exhaustive records of the whole previous medical histories of the decedents.

From the data of hospitals and the case-books of surgeons we can, indeed, extract particulars of the frequency of concurrence of multiple primary cancers in these special samples, but from such data we cannot determine whether the frequency is or is not less than "chance" might account for. An essential datum is lacking. Hence, in my opinion, statisticians should not be accused of overlooking a curious fact. The truth is that they are not in a position to say whether the fact is a fact.

So far I have discussed only what I take to be a direct inference from the experimental work, and have submitted that the statisticians, from lack of data, are unable to confirm or refute it. The suggestion that factors favourable to the development of cancer of one site may be unfavourable to the development of cancer in another site is surely not a direct inference from the experimental work, although inherently reasonable; up to a point, it can be tested statistically. I indicated in my last letter one of the lines upon which we have attempted to deal with the question, and more work remains to be done. This we shall hope to carry out, although I am under no illusions as to the difficulty of the task.

I must apologize to you, Sir, for the length of this letter; but it is right that the profession should understand that the statistical investigation of cancer is a laborious task, and those who pursue it have not the comfort of supposing that some brilliant stroke will put them in possession of an important and unsuspected truth. But the work must be done, and (like our experimental colleagues) we often have to waste time in blind alleys which we could not prove to be blind without visiting them.—I am, etc.,

Loughton, Feb. 20th.

MAJOR GREENWOOD.

UNQUALIFIED MEDICAL PRACTICE.

SIR,—The profession owes a debt of gratitude to Dr. Graham Little, not only for his courage and initiative in bringing forward his motion on unqualified practice in the House of Commons, but for his able and extensive writings combating the claims of the osteopaths in the *Times* and the *Spectator*.

Single-handed he has succeeded in giving a set-back to the osteopaths and their supporters, but this endeavour has involved him in some odium with the press. Surely the Council of the Association cannot allow such work to pass without notice, nor should the Divisions ignore the warning in your leading article (February 20th, p. 337) that the osteopaths will try again.

Their supporters are evidently wealthy and influential,

and many adherents have been gained by the recent press agitation, so that the next attempt will be vigorous and well designed, and will require the whole force of the profession to back Dr. Little, able and energetic though he be.—I am, etc.,

Warrington, Feb. 21st.

J. S. MANSON.

COMMON SENSE IN RELATION TO DOUBTFUL TUBERCULOSIS.

SIR,—In Dr. L. G. J. Mackey's admirable paper on "Common sense," published in the *BRITISH MEDICAL JOURNAL* of January 30th (p. 211), there is one passage to which, as one who has been concerned with tuberculosis for many years, I would venture to demur. Dr. Mackey says:

"But suppose we have made a mistake and labelled a man tuberculous who has nothing the matter with him except hæmoptysis from some unknown cause, have we done him any harm? No; a restful fresh-air holiday, a period of careful observation cannot do harm, and if we have tackled him properly he will not be alarmed or depressed."

Unfortunately this does not express the whole truth. Once a definite diagnosis of tuberculosis is made, the practitioner is under statutory obligation to notify the case, and this leads to official investigations. Apart from this, the "restful fresh-air holiday" under careful observation, prescribed for the patient, would generally connote a period of treatment at a sanatorium, which would proclaim the patient a "consumptive."

It would be possible to give many instances of cases in which very considerable harm had been done by a mistaken diagnosis of pulmonary tuberculosis. As a result of having labelled a man tuberculous a series of unhappy consequences may ensue. First, he may lose his employment; next, he may have to turn out of his house or room, because first his employer and then his landlord or landlady hear that he is "consumptive." These things have actually happened. At some subsequent period, though in good health, he may perhaps have difficulty in getting an insurance society to accept him. In truth, at the end of "a restful fresh-air holiday" he may find only too much cause to be alarmed or depressed.

With the well-to-do it may be different, but where we are dealing with persons who have to earn their own living—and they form the major part of the ordinary practice—I am confident that the better course to follow in all cases of doubtful pulmonary tuberculosis is to suspend judgement, keeping the patient meanwhile under most careful observation, until one can come to a definite diagnosis on reasonably sure grounds. I am glad to say that this is the view which is held by the chief medical officer of the Ministry of Health. In his annual report for 1920 (p. 89) Sir George Newman says: "The diagnosis of tuberculosis should be made by the tuberculosis officer with a due sense of the responsibility of his decision. . . . In doubtful cases he should lean rather to a negative than to a positive opinion, keeping the patient at the same time under careful observation."

Dr. Mackey's paper is most interesting, and his examples of the need of common sense in the various circumstances with which the general practitioner may be confronted will appeal to all, and I trust that he will not resent my venturing to draw attention to this one point where, in my opinion, he errs in the advice he gives the practitioner.

As regards the particular instance discussed by Dr. Mackey—namely, a slight hæmoptysis in a young person—we agree, of course, that in a very large proportion of cases the diagnosis would prove to be pulmonary tuberculosis. But, in common with many others, I have met with several cases of this sort, in which the hæmoptysis is unaccompanied by any other symptoms or physical signs, and in which nothing further has developed, and the patient has been known to be in perfect health some years later.—I am, etc.,

E. WEATHERHEAD, M.B.,

Alderley Edge, Cheshire,
Feb. 16th.

Tuberculosis Officer, North-East
Division of Cheshire.

FOCAL SEPSIS.

A Correction.

SIR,—May I correct a serious misstatement in the abridged report of my share in the discussion of this subject, which appears in the current number of the JOURNAL? In describing what might be considered as the pathological test of a "septic tonsil," the report states—

"Septic tonsils were associated with excess of polymorphonuclear leucocytes on the surface or in the substance of the gland, the presence of bacteria or debris in the gland not being of such great importance."

What I did state—and I quote from the typed copy of my remarks—was to the following effect:

"A tonsil is of pathological significance when one or more of its crypts contain an excess of polymorphonuclear cells, or when these are found making their way between the epithelial cells which line the crypts. The mere presence of bacteria in these recesses is no evidence of disease, but if and when such organisms pass through the epithelium into the lymphoid follicles of the glands then morbid conditions may arise, productive of local or systemic symptoms."

And again:

"... the small plugs of epithelial debris which can generally be squeezed from a tonsillar crypt have no pathological significance, although they may be of importance in that they provide a suitable medium for bacterial growth. Only when this assumes such a proportion as to destroy the normal epithelium and induces excessive polymorphonuclear migration will the portal be thrown open to invasion of the lymphoid tissue by the organisms and their toxins."

I think you will agree that these statements give an entirely different view of the matter from the inaccurate and distorted one which appears on page 324 of the JOURNAL, wherein no mention is made of the essential site and method by which infection enters the gland tissue of the tonsil.—I am, etc.,

London, W.1, Feb. 22nd.

HERBERT TILLEY.

* Peccavimus! It is sometimes possible to give the gist of sixteen lines in four, but here the attempt failed, and Mr. Tilley has not let us off.

COCCIDIA OF FISH IN HUMAN FAECES.

SIR,—I fear that in my letter which appeared in your last issue (February 20th, p. 347) my meaning may be subject to misinterpretation. When I wrote that I had pointed out to Dr. Thomson that I had suggested, in the manuscript of my forthcoming book, that the coccidia in question might be merely coccidia of fish I did not intend to imply that his work had been undertaken in consequence of this. As a matter of fact it was only after his work had been commenced and the significance of it realized by him that I told him my views on the subject. It is clear that the view as to the possible origin of these coccidia had occurred to both Drs. Thomson and Robertson and myself independently.—I am, etc.,

C. M. WENYON,

London, W.C.1, Feb. 19th.

Wellcome Bureau of Scientific Research.

SIR,—My attention has been called to the article by Drs. J. G. Thomson and A. Robertson regarding coccidia in fish, and, while their findings are very interesting, I protest strongly against their statement that "systematic zoologists" adopt "an attitude of superiority" towards medical men.

Anyone acquainted with the works of the zoologists Schaudinn, Grassi, Minchin, Doflein, etc., would not accuse such of neglecting or unduly criticizing the findings of medical men, and such statements are liable to have a bad effect on the workers in both medicine and pure science.

The one case which Drs. Thomson and Robertson refer to rather cryptically appears, illogically enough, to concern a worker who is engaged, not in systematic zoology, but in medical research, and in any case they might reflect that one does not condemn the whole race of birds for one butcher-bird.—I am, etc.,

J. S. DUNKERLY,

Lecturer in Protozoology and Helminthology,
University of Glasgow.

February 22nd.

CYESOEDEMA.

SIR,—The condition of eyesoedema described by Dr. A. Lendon in the BRITISH MEDICAL JOURNAL of December 19th, 1925 (p. 1179), is not of such rare occurrence as would appear from reading his article.

This general thickening of the cutis of the pregnant female, as already pointed out by me some time ago,¹ is, as a matter of fact, a common accompaniment in all pregnancies. But while it is well marked in some cases, especially in primiparae, it is in others of so slight a nature as almost to pass unnoticed.

According to Tandler and Grosz this "coarsening of the facial features and the thickening of the skin is due to a proliferation of the subcutaneous tissues." This is in keeping with the general proliferation and overgrowth in other tissues of the female during pregnancy—for example, thickening of the mucous membrane of the respiratory tract, which is probably responsible for the huskiness of voice and intractable coughs which are often met with in pregnancy. These proliferative changes are brought about by the functional increase in the physiological activity of the "hormone of growth" (anterior pituitary), obviously necessary at that period. It is therefore not surprising to find that, when the increased functional activity of the anterior lobe of the pituitary becomes excessive, as evidenced by a marked eyesoedema, the foetus should in such cases also be of greater weight than usual. This coincides with Dr. Lendon's observations on the cases he reported.

Dr. Lendon also states that eyesoedema did not recur in subsequent pregnancies which came under his notice. My experience is, however, that it does recur, though but rarely, and in such cases we get the condition known as progressive enlargement of the foetus.—I am, etc.,

S. E. KARK.

Capetown, Jan. 26th.

INDIVIDUAL OVERDOSE OF ULTRA-VIOLET RAYS.

SIR,—With reference to Dr. Paige Arnold's interesting letter in the JOURNAL of February 13th (p. 304), I must state that I have noticed the symptoms he describes in many patients treated during the last eighteen months with the quartz mercury vapour lamp. Such untoward symptoms—lassitude, depression, headache, etc.—I have always found to be associated with low blood pressure readings. Given an unduly low blood pressure one must expect such a patient to be intolerant to ordinary doses of ultra-violet rays.

By giving subminimal doses, possibly exposing only the face and forearms to the rays, with several days' intervals between the doses, these patients will often respond as to ordinary individual doses, and show increased energy, appetite, and a feeling of *bien-être*. There is a very definite "critical point" in the dosage of such cases, and this must not be passed.

Babies and toddlers who are thus sensitive often become irritable, sleepy during the day but restless at night, and begin to lose weight.

Dr. Arnold wonders whether ultra-violet radiation is as innocuous as is generally supposed, and suggests the possibility of untoward results such as followed on the pioneer use of x rays. We have it on the authority of Drs. Sequeira, Axel Reyn, and others with over twenty years' experience of the rays that no such dangers exist. I would, however, suggest one possible danger—that of cataract such as is met with in glass workers, tin-plate workers, chain-makers, and iron-smelters. Here cataract probably arises from insufficient protection against ultra-violet rays emitted from these molten substances affecting the worker improperly protected, and is not due to heat waves, as formerly supposed. It is known that coagulation of the crystalline lens occurs with exposure to ultra-violet rays even with wave-lengths of 2,800 to 3,220 A.U. This coagulation is only made evident in the presence of calcium chloride solution. These facts are significant, and at any rate strongly suggest that operators of ultra-violet lamps

¹ The Toxæmias of Pregnancy, South African Medical Record, April 8th, 1922.

—particularly the modern unhooded quartz mercury burners—should exercise great care in the protection of their eyes by really efficient goggles, lest in years to come “ultra-violet ray cataract” should claim its victims as did x-ray dermatitis in the past.—I am, etc.,

J. BELL FERGUSON, M.D., D.P.H.

Smethwick, Feb. 18th.

PREVENTION OF PUERPERAL FEVER.

SIR,—In the correspondence on puerperal fever I am surprised to see no mention of the large tracts of country which are without a district nurse. I have one district nurse in my practice, and she can only cover half the area, hence for the remaining half (which fortunately contains less than one-quarter of the population) I am dependent on the assistance of village women. This renders my work more arduous and infinitely more tedious, and yet I cannot claim even the paltry two guineas.

Could not the doctor's word be taken that medical assistance was required for a confinement without the production of a slip of paper from a person having the C.M.B., if such were not available? To cite one example: my car was out of order one day and I had to hire a car to attend a confinement six miles from my house; for this I was charged 30s. (including time waiting); I had the expense of subsequent visits; and for it all I received exactly nothing.

On the subject of puerperal fever generally I am glad to say that in six years' experience here I have not had a single morbid case, though I have had my share of placenta praevia, breech and transverse presentations, etc. I attribute this to good luck and the excellent experience I gained as house-surgeon to the Birmingham Maternity Hospital in 1917.

My procedure is as follows:

1. Ante-natal supervision and vaginal douching in cases of gross discharge.
2. When called to the confinement I make a very thorough first examination, and then never put a finger in again until I consider forceps or other intervention is required—if ever. The character of the pains and the condition of the patient, including her abdomen, usually give all the necessary information.
3. To avoid tears, as soon as the head is in the vagina I remove the forceps, and deliver very slowly by pressure on abdomen with left hand, and flexion and traction on head with right hand. It is almost always possible to deliver a primipara thus, without any lacerations.

The above remarks seem absolute platitudes, but it is evident from the statistics that some practitioners employ less successful methods.—I am, etc.,

ALETHEA J. EAMES, M.B., B.S.Lond.

Glynceiriog, Wrexham, Feb. 8th.

FINAL NURSING EXAMINATION.

SIR,—As one who has for many years been keenly interested in the training of nurses, and taken an active part in this most important work, I wish to add my support to the criticisms of Dr. Bradley and Mr. Morton in the last two issues of the *BRITISH MEDICAL JOURNAL* on the questions frequently set in examinations for nurses.

I would go further and criticize the majority of so-called “nursing” books on the market. Their number is legion, and I have taken the trouble to peruse a great number of them, and have in most cases been struck by the absence of reference to nursing from cover to cover. They are quite frequently little more than anatomy, physiology, medicine, and surgery dished up in “potted” form, and a vast amount of the information can be of no value at all from the nursing point of view and useful only for examination purposes.

The *Handbook for Mental Nurses*, the book officially recognized by the Royal Medico-Psychological Association for training nurses for this association's nursing certificate, although recently revised and containing much more useful information with regard to points on nursing than any former edition, is still, in my opinion, a serious offender by devoting space to a description of the five types of nerve cell found in different layers of the cerebral cortex and a diagram showing the same. What useful purpose can this serve?

At a recent General Nursing Council examination, at which one of my nurses sat and passed, one of the questions

asked by the nurse examiner in the oral part of the examination was, “How to render water from a pond polluted by typhoid fit for drinking purposes.” This surely should not be a matter for a nurse and should never be left in her hands even under war conditions; therefore why examine her on such subjects? Now we have a General Nursing Council it cannot be too strongly insisted upon that questions set in its examinations must have some practical bearing on nursing and not merely a test of the candidate's knowledge of medicine, surgery, or public health.—I am, etc.,

R. EAGER,

Medical Superintendent, Devon
Mental Hospital.

Exminster, Feb. 21st.

SIR,—I am in complete agreement with Dr. Bradley's letter (February 13th, p. 305). I was present at a meeting in London at which the syllabus was discussed, and was able to produce letters from would-be probationers which proved clearly that the general standard of education was distinctly below par. Dr. Bradley writes: “The matter is a serious one for small provincial hospitals”; I should like to add, and far more serious for the general public. I know a nurse who is in great demand who could not even attempt an answer to the questions quoted by Dr. Bradley, but who can move a patient without causing pain or discomfort, who can carefully attend to a patient's back and prevent bedsores, who never talks of wonderful cases she has nursed and saved from the jaws of death; but who carries out the instructions of the medical man attending the case to the letter. We are bringing up a new type of nurse who uses words which she cannot spell correctly (as I know too well, having read many nurses' notes), and the meaning of which is as intelligible to her as if you placed the *Medea* before her and asked her to translate it. I am really sorry for the nurses, because we shall ere long have a profession to which Pope's lines will assuredly apply:

The bookish blockhead, ignorantly read,
With loads of learned lumber in his head.

If Pope had lived to-day he would not have objected to the change of “his” to “her.”—I am, etc.,

S. J. ROSS,

February 14th.

Honorary Surgeon, Bedford County Hospital.

LORD LISTER'S BIOGRAPHY.

SIR,—A German translation of Sir Rickman Godlee's biography of Lord Lister has been published, which claims to be “the only authorized translation.” It was only “authorized” on condition that it should be approved by him before publication, and this condition was not fulfilled. As his executrix I desire it to be known that neither he nor his representatives are in any way responsible for the accuracy of it.—I am, etc.,

Whitchurch, Oxon., Feb. 16th.

JULIET M. GODLEE.

Obituary.

CHARLES DORRINGTON BATT, M.B., M.R.C.S.,
Witney, Oxon.

THE death of Dr. C. Dorrington Batt on February 14th has removed a fine representative of the older school of country general practitioner. He was born at Witney in 1845, and on leaving Epsom College served a year's apprenticeship to a doctor at Guildford. In 1863 he entered St. Bartholomew's Hospital, and obtained the diplomas of M.R.C.S.Eng. and L.S.A. in 1867, graduating M.B.Lond. with first-class honours in 1868. For the next three years he held the post of house-surgeon to the Sheffield General Infirmary; then, owing to a breakdown in health, he sailed twice to New Zealand as a ship surgeon. In 1872 he settled in practice at Witney, and for thirty-one years, until his retirement from active work in 1903, he was a valued friend and medical adviser to many families in the town and neighbourhood.

Besides his professional duties Dr. Batt found time for many other activities. He had been chairman of the urban district council, churchwarden, and on two occasions

bailliff, and for many years his counsel and co-operation could be depended on in everything that concerned the welfare of the district. In 1893 he was made a justice of the peace for the county of Oxford. In his younger days he held a commission in the Volunteers, and looked forward with delight to the annual training in camp. He was keenly interested, too, in the work of the St. John Ambulance Association, and took infinite pains to make his first-aid classes practical and interesting. Outside his professional and public work he had many interests and pleasures. He loved his home and his children, and the outdoor life of the country; he swam in the river every summer morning, was a keen cyclist, an enthusiastic horseman, and a well known figure in the hunting field. His wife's death in 1905 was a blow from which he never fully recovered, and thenceforward gradually failing health limited his activities. During the early days of the war he was, however, able to act as commandant of the local Red Cross V.A.D., and assisted in the maintenance of the Belgian refugees sheltered in the town. In 1919 he was extremely ill, and had a severe operation, and the remaining years of his life were passed as an invalid.

Dr. Batt's death, after a long and full life of service to his fellow-men, breaks a professional connexion between his family and Witney which had lasted for nearly two centuries. The practice was started by Augustine Batt, apothecary, who was born in Wiltshire in 1713 and was buried at Witney in 1779; it passed to his son Edward (1742-99), who had studied medicine at St. George's Hospital. An old ledger covering the years 1774 to 1778 contains many interesting entries, among others a list of "inoculations," presumably direct inoculations with lymph from small-pox vesicles. Edward was succeeded by Augustine William Batt (1774-1847), who seems to have joined his father in partnership, for a ledger dated 1795 is headed "Batt & Son." In the next generation, Edward Augustine (1801-53) carried on the practice, and was the father of a family of seventeen, of whom three sons became doctors and practised at Witney. Edward Batt succeeded to the family practice, and in 1854 entered into partnership with his brother Augustine. The third son, Charles Dorrington Batt, the subject of this memoir, was in partnership with Augustine until the latter's death in 1883. He himself, the last of this large family, had eight children, of whom two (Dr. Bernard Batt of Bury St. Edmunds and Dr. J. D. Batt, M.C., of Wickhambrook) are members of the medical profession.

M. B. R. SWANN, M.D., D.P.H.,

Demonstrator in Pathology, University of Cambridge, and Fellow of Caius College.

We regret to record the death, on February 16th, of Dr. Meredith Blake Robson Swann, as the result of a streptococcal septicaemia contracted while making a *post-mortem* examination. He was the son of Mr. Frederic Swann, at one time headmaster of Ilkley Grammar School, and subsequently a member of the staff of the *Times*. On leaving Dulwich College, Meredith Swann was elected to a scholarship at Caius College, and matriculated in October, 1912. He was placed in the first class in the Natural Sciences Tripos in 1914, and proceeded to King's College Hospital. He obtained the diplomas M.R.C.S., L.R.C.P.: in 1917, the D.P.H. in 1920, and graduated M.B., B.Ch.Camb. in 1921, proceeding M.D. in 1924. After holding the posts of house-physician in the children's department and assistant casualty officer at King's College Hospital, he was gazetted as surgeon lieutenant to H.M.S. *Bacchante*, when she was stationed in the Atlantic and off the West Coast of Africa. In 1919 he returned to Cambridge, and was shortly afterwards appointed demonstrator in pathology. In 1923 he was elected to a Fellowship at Caius College, and was awarded the Raymond Horton Smith prize for the best M.D. thesis. He married in 1917 Marjorie, daughter of Mr. Alfred H. Dykes of Beckenham.

His colleagues in the department of pathology and the medical school have lost a friend who was very dear to them. His pupils have lost a teacher who has had a great influence on the students of Cambridge University during the years which have followed the war. Swann took a deep

and varied interest in the experimental side of pathology and had published papers on the germination period of mortality of anthrax spores, and on the effects of γ ray on the functional activity of various organs. His interest in morbid histology and histological methods was very keen and during the last twelve months he was engaged on a very complete and careful study of the microscopic changes associated with an epizootic disease of rabbits. As a teacher Swann's success was beyond question, and he was never more at home than in the classroom or happier than when surrounded by a group of students who had left their places to hear what he had to say about some specimen or experiment. He was keenly interested in teaching, and always determined to make every class a success. He had a great capacity for organization, and found full opportunity for the exercise of his powers in the arrangement of the class work in general pathology for Part II of the Natural Sciences Tripos. The planning of a course in experimental morbid histology for the Tripos was just the kind of work which appealed to him, and he devoted himself with great enthusiasm and success to the task. Swann's influence on medical students was not limited to his work in the department of pathology; a supervisor of medical studies at Caius College he came into contact with a large number of men who were reading for the medical degree. In college, as in the laboratory, his popularity was the result of the genuine and untiring interest which he took in his pupils. His advice was readily sought and as readily obeyed, and lost nothing of its effect from the vigorous brevity with which it was often delivered.

His death, at the early age of 32, is a grievous loss to his college, the department of pathology, and to the university. The funeral service was held on February 19th at Cambridge; the first part was conducted in Caius College Chapel by the Dean, assisted by Canon E. S. Woods, and the Master, Sir Hugh Anderson, M.D., read the lesson many members of the university attended. The burial followed at Trumpington. H. R. DEN.

Universities and Colleges.

UNIVERSITY OF CAMBRIDGE.

SIR HUMPHRY ROLLESTON, Bt., Regius Professor of Physics, has been appointed to represent the University on the general council of the Fellowship of Medicine.

At a congregation held on February 19th the degree of B.Ch. was conferred on J. C. Hogg and R. L. Rhodes.

UNIVERSITY OF BRISTOL.

THE dissertation on "Primitive instincts in insanity," submitted by Elizabeth Casson, M.B., Ch.B., has been approved by the examiners.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.

DIVISION OF TROPICAL MEDICINE AND HYGIENE.

THE following passed the school examination at the termination of the seventy-ninth session (October, 1925, to February, 1926):

*B. M. Morris (Duncan medal). *W. A. Young, *H. L. Batra, *T. Y. L. *T. P. Noble, *A. K. El Shurbagi, *M. A. H. Attia, *J. C. P. *A. G. ... Abdel-Khalik, S. C. G. ... W. H. ... Mosteri, E. A. Penny, E. F. ... B. N. ... E. K. Will, E. Strathern ... Claxton ... and M. A. H. Azim, A. S. ... M. B. I ... J. Woodhouse, B. E. Khoo ... Douglas ... J. D. L. Perera, K. W. Todd, E. Burke, H. W. Brassington, D. W. G. Faris, R. McEagans, M. Rustonjee, J. J. O'Grady, C. M. Churches ... Sherwood Hall, J. J. Keevil, G. D. Gordon, C. S. Wyde, T. V. FitzPatrick, Y. N. Lal, W. L. Gopsill, C. R. Subryan, T. James ... R. A. Heatley, R. Huey, V. F. Dougherty, P. L. Gray.

* With distinction.

SOCIETY OF APOTHECARIES OF LONDON.

THE following candidates have passed in the subjects indicated:

Surgeons—J. Dywien, V. Escovar, A. C. Hill, J. E. Howard, J. Mindess, L. A. Rostant, J. Shibko, Y. R. Smith, ... W. Hayward, W. Johnson, ... Weeber, J. M. T. Whitby, ... H. St. Johnston, G. H. Pereira, J. Shibko, J. W. Whitney, ... N. H. C. Allen, F. W. Barton, V. G. Crowley, M. Escovar, ... H. I. Jones, D. P. Mitra, G. H. Pereira.

The diploma of the Society has been granted to Messrs. T. F. Clifford, V. G. Crowley, E. W. Hayward, J. Mindess, G. H. Pereira, L. A. Rostant.

Medical Notes in Parliament.
[FROM OUR PARLIAMENTARY CORRESPONDENT.]

THE House of Commons has this week been again chiefly occupied with Supplementary Estimates. In addition the Estimates for the Air Force have been introduced. An Adoption of Children Bill was the business for February 26th. On a private member's motion war pensions administration, including the medical side, was debated on February 23rd, and the House rejected a proposal to set up a Select Committee on the subject.

General Medical Council.

The Minister of Health, replying to a question by Mr. Storry Deans, said he had considered the suggestion that the General Medical Council ought to contain a lay representative, and that the power of nomination conferred on the Crown by the Medical Act of 1886 should be exercised by appointment of laymen as and when vacancies arose. Mr. Chamberlain added that he would take an early opportunity of consulting the Earl of Balfour, Lord President of the Council, on this matter.

Parliamentary Medical Committee.

The Parliamentary Medical Committee, at its meeting on February 17th, decided to give a general invitation to Peers and members of the House of Commons to attend a meeting on February 24th at which Lord Dawson of Penn would speak on the relations of the medical practitioner, the General Medical Council, and the public. The Medical Committee received a deputation from the Medical Practitioners' Union on the Coroners Bill, which the Government has introduced into the House of Lords this session. The deputation suggested amendments in the 1925 text of the bill. The Committee took no decision pending the introduction of the bill. Dr. Harry Roberts brought forward certain criticisms of the proposals for reform of the Poor Law which the Ministry of Health has circulated. He suggested an extension of the National Health Insurance system to cover the needs of those persons not in institutions for whom provision is now made by the Poor Law medical service. The Medical Committee also discussed the Opticians Bill, of which a draft has lately been issued, and considered it as it would affect the ordinary general practitioner. The Committee felt that considerable amendment would be required before the bill could obtain the support of medical men, but the subject was left for further consideration, in view of the fact that the British Medical Association was preparing a memorandum on the bill, and also to await the opinion of the Council of British Ophthalmologists.

Indian Medical Service.

On February 22nd Colonel Applin asked the number of Indian subordinate medical officers qualified for promotion to commissioned rank in the Indian Medical Service awaiting gazette; and whether the Under Secretary for India could expedite the gazetting of these officers at an early date. Earl Winterton replied that he was not precisely aware to what class Colonel Applin referred. If he would supply further particulars the case should be examined.

Lord Winterton, answering Mr. R. Richardson, said the proposals made by the Government of India with a view to reserving the civil posts of the Indian Medical Service for Europeans were still under consideration and he could make no statement. No final orders had yet been issued on the recommendations of the Lee Commission regarding this service.

Maternal Mortality.

Answering Mr. Groves, Sir Kingsley Wood said there were 758,131 births in England and Wales in 1923 and 729,923 in 1924. He gave the following statistics of maternal mortality for the same years:

	1923.		1924.	
	No.	Rate per 1,000 births registered.	No.	Rate per 1,000 births registered.
Deaths of women classed to pregnancy and child-bearing	2,892	3.81	2,847	3.95
Deaths of women not classed to pregnancy and child-bearing but returned as associated therewith	754	1.01	851	1.17
Total	3,656	4.82	3,698	5.07

Sir Kingsley Wood further said that the Minister of Health was unable to say there had as yet been any general improvement in the maternal mortality in rural, textile, and coal-mining areas, but the figure for 1925 was not available. Mr. Groves asked whether it was the custom of all medical officers of health to investigate all maternal deaths due to childbirth and all cases of puerperal fever, whether fatal or not. Sir Kingsley Wood replied that a circular issued by the Ministry of Health in June, 1924, impressed on local authorities conducting maternity and child welfare schemes the desirability of competent medical investigation into both. The extent to which this was adopted varied in different areas.

Small-pox.

Mr. Chamberlain, answering Major MacAndrew, said that in areas invaded by small-pox the usual practice of local authorities was to urge the importance of vaccination, and to announce the facilities available for vaccination free of cost to all who desired it, but there was no statutory provision for compulsory vaccination except in the case of children whose parents had not made declarations of conscientious objection. Answering Mr. Whiteley, Mr. Chamberlain said there was no present intention of amending the vaccination laws. Answering Mr. H. Williams, he said that, according to information available, 2,006 cases of small-pox were notified in the county of Durham from January 1st, 1925, to February 12th, 1926, of which 1,970 had so far been classified by vaccinal condition. At the time of infection 1,528 were unvaccinated, 429 had been vaccinated at some time, and the condition of 13 was doubtful. Of the 429, none was under 15, and only one had been revaccinated—namely, a man aged 51, who had been vaccinated in infancy and again at the age of 14.

Mr. Lansbury, on February 22nd, asked the Minister of Health whether he was aware that the outbreak of small-pox in the years 1901-02 coincided with an increase in the number of vaccinations performed in consequence of the passing of the Vaccination Act, 1898; and whether he would state the number of cases of small-pox notified in the years 1897, 1898, 1899, 1900, 1901, 1902, 1903, and 1904, and the number of infants vaccinated out of every hundred born in each of those years. Sir Kingsley Wood replied that it was the fact that the total numbers of vaccinations and revaccinations performed during 1901 and 1922, at the cost of the rates, was considerably in excess of the numbers in previous years. But, as the primary object of the Vaccination Act, 1898, was to exempt from penalties parents who obtained certificates of conscientious objection to vaccination, this increase could not, in the opinion of the Minister of Health, be attributed to the passing of that Act, but rather to the fact that when small-pox was prevalent, as in 1901-02, it was usually found that large numbers of persons sought the protection afforded by vaccination. As regarded the last part of the question, figures were not available showing the number of cases of small-pox notified during the years in question, but the following statement gave the percentage of vaccinations to births in each of these cases.

Year.	Percentage.	Year.	Percentage.
1897	62.4	1901	71.4
1898	61.0	1902	74.8
1899	65.4	1903	75.4
1900	68.7	1904	75.3

Sir Kingsley Wood informed Mr. Groves, on February 22nd, that the Minister of Health would communicate to the Committee on Vaccination for their consideration the following suggestions made by the hon. member: The precise nature of the disease from which vaccine lymph was derived and how its nature was determined; what was a successful and efficient vaccination and for how long it could be guaranteed to remain so; how frequently it had been found possible to repeat vaccination on the same person; the relation of the possibility of frequently repeating vaccination to the question of immunity; and the means recommended for ascertaining whether the immunity afforded by vaccination had lapsed.

On February 22nd Mr. Charles Williams asked the Minister of Health what steps he was taking to inform the public of the efficiency of vaccination against small-pox, particularly in those areas where there was any sign of the disease. Sir Kingsley Wood replied that it was the duty of the local authorities of areas in which any case of small-pox occurred to urge the importance of vaccination and the efficiency of this method of protection against small-pox; and it was the usual practice of the local authorities to take these steps. Mr. Lansbury asked whether it was not a fact that some medical men in the two districts in the North, where it was suggested that small-pox was prevalent, disagreed entirely, and thought that it was not small-pox at all. Sir Kingsley Wood replied that notice had better be given of that question. As Mr. Lansbury knew, in the particular area where there was an industrial dispute the outbreak of small-pox was not so severe as in adjoining areas.

Answering Mr. Trevelyan Thomson, on February 22nd, Mr. Neville Chamberlain said he was aware that the disease which was being diagnosed as small-pox in Northumberland and Durham, when not complicated with any other disease, was not causing any deaths at all. In view of the fact that the majority of the cases were unvaccinated persons, his medical advisers were certain that the disease was small-pox. He referred Mr. Thomson to paragraph 62 and following paragraphs of the annual report of the chief medical officer for 1924.

Foot-and-Mouth Disease.

On a Supplementary Estimate for the Ministry of Agriculture, Mr. Guinness (Minister of Agriculture) said that imported hay and straw might be a source of infection of foot-and-mouth disease, but the Ministry had strong evidence against migratory birds, and even stronger against vegetables brought from the Continent and meat from the Continent and the Argentine. Outbreaks

had been traced to the feeding of pigs with swill made from unboiled vegetables of foreign origin or parings of imported meat. Sir Stewart Stockman was on his way to the Argentine to see whether effective steps were being taken to prevent carcasses in the infective stage being brought into this country. There was evidence of two strains of infection, and animals which were immune to one strain were not necessarily immune to the other. All this was being inquired into by the Leishman Committee. The developments under the Tuberculosis Order had been satisfactory. Local authorities had taken it up energetically, and more cattle had been slaughtered than was anticipated. They had reason to believe that the worst had been dealt with first. The measures were only aimed at stamping out the actively infectious cases—cattle which fell into emaciation and cattle suffering from tuberculosis of the udder.

Mr. Runciman complained that the Ministry of Agriculture's new laboratory had been starved of money. They had hoped to recruit for it, not only those skilled in veterinary science, but some young men trained in human medicine.

Replying to the debate, Mr. Guinness said that Dr. Shaw's preventive for foot-and-mouth disease had been tested after he had been given fair facilities to assist in it. The farmers for whom the test was made were satisfied that the substance was not really a preventive.

Pensions.

On February 23rd Mr. Stephen Walsh moved that a Select Committee of the House of Commons be appointed to inquire into the general administration and practice of the Ministry of Pensions, with special reference, among other subjects, to final and erroneous awards and the advisability of appointing an independent court of medical appeal for the hearing of appeals against decisions of the entitlement and assessment appeals tribunals. He said that the Labour Government would have set up such an inquiry if it had been longer in office. Colonel Assheton Pownall moved an amendment declaring that such reopening of the settled principles of war pensions administration would be undesirable. He advocated a reduction in the number of medical boards.

Dr. Drummond Shiels condemned the removal of the Scottish Regional Headquarters from Edinburgh to London, on the ground of administrative efficiency and economy, and also on the analogy of Scottish autonomy in health, education, agriculture, etc. He asked for that proposal to be abandoned. He said that there was much dissatisfaction throughout the country with the administration of pensions. He condemned the rigidity of final awards, and said that no medical man could say that in twenty-six weeks, or a hundred and four weeks, a sick or injured man would be exactly and entirely restored to health. The principle of final awards was bad, and the ex-service man should be able to have his case reassessed at any time on his own application. The clause in the warrant dealing with the definition of "widow" was intended to be a safeguard against designing females marrying dying ex-service men, but was being used to deprive bona-fide widows and their children of their just due. If the disability from which an ex-soldier died could be shown, after much legal and medical consultation, to have possibly started before he married, there was no pension. That was not what the public would wish. Tuberculous ex-service men needed more care. He advocated the restoration of the special diet allowance and development of special industrial colonies. A select committee could do no harm, and it would satisfy public opinion.

Major Tryon, replying to the debate, said the most frequent complaints were from pensioned men, who said they wished to have no more medical boards and to have their pensions settled for life. The Ministry was prepared to deal with hard cases even beyond the seven years' limit. He saw no need for a select committee.

Mr. Walsh's resolution was rejected by 256 to 161.

Major Tryon, Minister of Pensions, told Major Cohen that in 1925 1,274 applications for sickness grants were made by widows or orphans, and 230 awards were made. He was issuing fuller information for the guidance of such applicants.

Tuberculosis in the Services.—In reply to Dr. Davies, Sir L. Worthington-Evans, Secretary for War, said the number of soldiers invalided from the army on account of pulmonary tuberculosis during 1923 was 218, during 1924 174, and during 1925 approximately 203. The number of cases not attributable to military service could not be stated, nor were figures available in regard to officers. In reply to Captain Fairfax, Mr. J. C. Davidson, Secretary of the Admiralty, said the ratio per 1,000 of men invalided from the navy for tuberculosis was 1.96 in 1922, 1.61 in 1923, 1.57 in 1924, and 2.29 in 1925. He was satisfied that all reasonable precautions were enforced to prevent the spread of this disease in the navy.

Tuberculin-tested Cows.—On February 22nd Dr. Fremantle asked the Minister of Agriculture if he could give figures showing the number of milch cattle subjected to the tuberculin test within the past year, and the number that had reacted. Sir Kingsley Wood, Parliamentary Secretary to the Ministry of Health, said that he had been asked to reply, since there were very few official records of tuberculin tests other than those carried out for the purpose of the Milk (Special Regulations) Order. The number of cows tested for the purpose in 1924 was about 6,000, the majority of which had already passed the test on one or more previous occasions, and the number which reacted

in that year was 732. In 1925 the number tested and reacted was nearly 7,500, but he was not yet able to state the number of reactors.

Inquests after Operations.—Mr. Ellis Davies asked the Secretary of State for the Home Department what was the rule with regard to holding inquests on persons dying following an operation; whether inquests were confined to cases where the person died under the operation; and, if so, whether he would consider the desirability of providing, in view of the increased number of operations, that inquests should be held in all cases where a person died within, say, twenty-four hours of an operation. The Home Secretary replied that the circumstances in which it was obligatory upon a coroner to hold an inquest were indicated in Section 3 (1) of the Coroners Act, 1887. It was for the coroner concerned to decide whether the obligation applied to any particular case. Registrars of deaths had been advised by the Registrar-General that the attention of coroners should be called to any death which was shown by the certificate, or by information given, to have occurred under or in immediate connection with an operation, or before recovery from the effects of an anaesthetic, or after an operation necessitated by injury. Mr. Chamberlain informed Mr. Ellis Davies that information was not available giving the number of persons who died as a result of the following medical operations.

Insect Bites.—Mr. Neville Chamberlain, in reply to Mr. Herbert Williams, said the number of deaths in England and Wales from insect bites during 1925 was not available. He was advised that so far as could be ascertained the number of insects whose bites were deleterious to health was not increasing. In reply to Mr. Forrest, Mr. Chamberlain said he had received a suggestion that an Order should be made that all mosquito-infested ponds and stagnant waters should be deemed a common nuisance. He had no power to make such an Order. The question whether a pond was a nuisance was one to be determined by the court in any proceedings instituted by the local authority.

Coal-Gas Poisoning.—On February 23rd Sir Burton Chadwick, Parliamentary Secretary to the Board of Trade, informed Mr. Scurr that special provision was made for recording particulars of deaths attributed to poisoning by gas supplied for use by the public. During 1925, in the areas supplied by the three London gas companies, there were 27 such deaths, in which either an error of verdict or a verdict of accidental death was returned. He was aware that the use of water gas in towns' gas increased the proportion of carbon monoxide beyond that found in ordinary coal gas. The matter was reported upon in great detail in 1921 and the Government was watching the position most carefully and closely, but at present it was not considered that a further inquiry would be useful.

Training of Scottish Midwives.—On February 23rd Dr. Shiels asked the Secretary for Scotland, in view of the new regulations for the training of midwives coming into force in May of this year and the difficulty of meeting the full extra costs by increased fees to pupil nurses in the Scottish maternity hospitals, if he would try to secure for Scotland the same grants-in-aid as were promised for similar hospitals in England and Wales. Sir J. Gilmour, Secretary for Scotland, said he regretted that he was unable to take the action proposed. In view of the interest of members in the subject and the difficulty of dealing adequately with it by the method of question and answer, he had had an explanatory memorandum prepared which he was forwarding to Dr. Shiels, and which he would make available to members interested. At the same time, he fully appreciated the special difficulty with which the maternity hospitals might be faced, and was keeping it in view in considering the report of the departmental committee on the hospital position in Scotland.

Physique of Country Children.—In reply to Mr. Scurr, the Duchess of Atholl said the report of the Chief Medical Officer to the Board of Education, while stating that there was a substantial degree of physical impairment among rural children, added there were good grounds for believing that on the whole there was improvement, and in some areas great improvement. Perseverance was needed along the lines on which the Board had worked in the past, especially in replacement of unhealthy school buildings, rather than in any new departure of policy. The Minister for Education was considering whether he could usefully tender any advice to local authorities as regards the Chief Medical Officer's recommendation that children under 6 years of age in rural areas should be discouraged from attendance at school in certain circumstances.

Women in Industry.—Mr. McLean asked the Minister of Labour whether a number of women who were signing at Govan Employment Exchange had been called upon to undergo a medical examination by doctors at the exchange; what were the reasons for this and its purpose; whether the medical examination was compulsory; if not, whether women so called upon could refuse without prejudice to their claims for benefit, and under what statute the Ministry of Labour was acting. Sir Arthur Steel Maitland, Minister of Labour, said Mr. McLean referred to a trial which was being carried out with his consent by the Industrial Fatigue Research Board. Acceptance of the test, which was made by a woman doctor and a woman assistant, was voluntary, and did not affect benefit in any way. The proposal of the Board had been considered by a conference in Glasgow of women representatives of local employment committees, who thought that it would be useful. Mr. McLean asked whether women who went to the exchange were told that they would be examined by a woman doctor.

without being told that it was voluntary and were led to assume that if they did not undergo medical examination their claim to benefit would be prejudiced, and whether the Minister would withdraw his consent to the experiment. Sir A. Steel-Maitland said Mr. McLean must not infer that women were led to undergo examination without being told that it was voluntary. He would send to Govan to ensure that the fact should be made clear that the experiment was voluntary and unconnected with benefit. On the other hand, he said willingly that inquiries by the Fatigue Research Board were for the general good, and he would be very sorry to stop them. These answers were received with protests from the Labour benches, and Mr. McLean demanded to know by what right the Minister asked women to undergo, even voluntarily, this examination in a Government office set aside as an employment exchange. He asked leave to move the adjournment of the House to call attention to "the illegal action of the Minister of Labour in placing the employment exchanges at the service of the Industrial Fatigue Research Board, and in asking unemployed women to undergo medical examination in a manner which leads these women to believe they would lose benefit if they refused." The Speaker would not accept the motion, and informed Mr. McLean that if there had been any illegal action the courts were open.

Social Hygiene.—A memorandum on the imperial aspect of social hygiene, signed, among others, by Dr. Vernon Davies, Dr. Fremantle, Dr. Thomas Watts, Dr. Haden Guest, and Sir Richard Luce, has been considered by the Parliamentary Medical Committee and circulated to members of Parliament. It urges members to keep before the Government the importance of allocating a percentage of the East African Development Loan to enable adequate medical measures to be taken in areas where development work is undertaken; the importance of immediate action for the improvement of the medical service in the West Indies; the need for adequate measures against venereal disease there and in the Straits Settlements; and the need for contributions from the Imperial Government towards the cost of port clinics when the Colonial Governments cannot adequately provide these.

Notes in Brief.

The anomaly whereby graduates of the University of London who are women are debarred from the parliamentary franchise until they attain the age of 30 can, the Home Secretary informed Dr. Little, be considered by the proposed conference on the general question of the franchise of women.

Reports of medical officers of health for 1923 show that 14,367 houses in England and Wales were reported during that year as unfit for human habitation. The number condemned but still occupied cannot be given.

No conference has been called of countries within the British Empire to decide a united policy on anthrax. The question cannot come up for discussion at the next International Labour Conference.

Between November 1st, 1925, and February 17th, 1926, 172 outbreaks of foot-and-mouth disease were confirmed in England and Wales.

In England 35 institutions provide full-time courses of trade instruction for the blind, and in Wales 3. Eight institutions in England provide part-time courses for the blind.

During the last week of 1925, 206,800 persons, excluding casuals, were receiving relief in institutions under Poor Law authorities in England and Wales.

There were in Glasgow on April 1st, 1925, 1,517 blind persons, exclusive of 96 of school age. The present numbers probably exceed this total.

There were 1,048 fatal accidents in the coal and iron mines of the United Kingdom in 1925, and 1,134 persons lost their lives.

The Services.

HONORARY SURGEON TO THE KING.

COLONEL A. N. FLEMING, D.S.O., I.M.S., has been appointed Honorary Surgeon to the King, with effect from June 9th, 1925, in succession to Colonel P. Dee, I.M.S., who has retired.

PROMOTION EXAMINATIONS IN THE R.A.M.C.

THE following campaign has been selected for examinations of officers for promotion in 1927: For majors of the Royal Army Medical Corps (March and October examinations), the Great War on the Western Front from the beginning of the Somme battles, 1916, to the end of the operations at Cambrai in 1917, as covered by the official history of the war, *Medical Services—General History*, vol. ii.

Surgeon Vice-Admiral Sir Robert Hill, K.C.B., K.C.M.G., who retired from the post of Medical Director-General of the Navy in 1923, has been awarded the Good Service Pension of £100 a year, in succession to the late Inspector-General, Sir Henry Norbury, K.C.B.

Medical News.

THE anniversary dinner of the Medical Society of London will be held at the Grand Hotel, Trafalgar Square, W.C., on Friday, March 12th, at 7.30 p.m.

ON May 20th Professor A. V. Hill, Sc.D., F.R.S., will deliver the Croonian Lecture before the Royal Society on the laws of muscular motion.

THE ninth Silvanus Thompson Memorial Lecture will be delivered by Sir John Thomson-Walker, F.R.C.S., on radiology in urinary surgery, at a general meeting of the Röntgen Society to be held in the Barnes Hall of the Royal Society of Medicine, 1, Wimpole Street, W.1, on Tuesday, March 30th.

THE Overseas Medical Officers' annual reunion dinner will be held at the Exchange Hotel, Liverpool, on Thursday, March 4th, at 7.30 p.m. Tickets, price 12s. 6d., may be obtained from the honorary secretary, Dr. John William Burns, 49, Rodney Street, Liverpool.

UNDER the auspices of the British Institute of Philosophical Studies a lecture will be delivered at the Royal Anthropological Institute, 52, Upper Bedford Place, W.C., on March 5th, at 5.30 p.m., by Professor T. H. Pear, on the concept of the unconscious.

THE Fellowship of Medicine announces that on March 4th, at 5 p.m., a lecture will be given on dyspepsia by Dr. E. P. Poulton, at 11, Chandos Street, W.1; this lecture is free to all members of the medical profession. Beginning on March 1st there will be a special series of demonstrations on the diagnosis and treatment of disease of the eye at the Royal Eye Hospital, Southwark, at 3 p.m. daily, for a fortnight. On Tuesdays and Thursdays throughout the month there will be a special course in bacteriology at the Westminster Hospital, and on March 8th the Chelsea Hospital for Women will commence a three weeks' daily course in gynaecology. From March 15th to 27th the Brompton Hospital will hold an all-day course in diseases of the chest; and beginning on March 16th the London School of Tropical Medicine will give a series of eight clinical demonstrations, extending over four consecutive weeks, on Tuesdays and Thursdays at 2 p.m. The Hampstead General Hospital is holding a special post-graduate course for practitioners from March 15th to 26th with daily sessions from 4.30 to 6 p.m. Copies of all syllabuses and of the general course programme may be had from the secretary of the Fellowship of Medicine, 1, Wimpole Street, W.1.

THE King has granted to Dr. Arthur E. Scott, assistant medical officer in the Egyptian Ministry of Public Health, authority to wear the Insignia of the Fourth Class of the Order of Ismail conferred upon him by the King of Egypt in recognition of valuable services rendered.

DR. W. NORWOOD EAST has been appointed inspector of retreats under the Inebriates Acts.

THE January number of the *Kenya Medical Journal* is almost entirely taken up with a report on the mosquito breeding areas within the Nairobi municipality, compiled by Mr. V. G. L. van Someren and Dr. H. S. de Boer, medical officer of health for the district.

AT the University of Geneva 819 students have been enrolled this winter session. Of these 77 were Germans, 33 Poles, 23 French, 18 Russians, 17 Jugo-Slavs, 15 Hungarians, 13 Bulgarians, and 13 Egyptians.

THE late Dr. William Frank Colclough of Sidmouth has left estate valued at £32,174, with net personalty £26,439. In his will he stated that he desired his body to be sent to the pathological department of Guy's Hospital for a pathological investigation, because, when 9 years of age, he was trephined for middle meningeal haemorrhage, and he thought his skull and brain might be of interest for the museum. He bequeathed £50 to the pathological department for this purpose and £200 to the anatomical department. Sidmouth Cottage Hospital receives under his will £250, in addition to his microscope and instruments; his medical books he bequeathed to the Devon and Exeter Medico-Chirurgical Society.

MR. G. BUCKSTON BROWNE has presented to the Manchester University a bust of his father, Dr. Henry Browne, for many years a teacher in the Pine Street and Faulkner Street Royal School of Medicine, and physician to the Manchester Royal Infirmary.

THE infantile mortality in Holland was 5.7 per cent. in 1919-23, as compared with 12.5 per cent. in the previous fifteen years.

PROFESSOR LÜHE has been elected successor to Professor Wechoelmann as director of the department for skin diseases at the Rudolf-Virchow Hospital, Berlin.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.**

ORIGINAL ARTICLES and **LETTERS** forwarded for publication are understood to be offered to the **BRITISH MEDICAL JOURNAL** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring **REPRINTS** of their articles published in the **BRITISH MEDICAL JOURNAL** must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to **ADVERTISEMENTS**, as well as orders for copies of the **JOURNAL**, should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBERS** of the British Medical Association and the British Medical Journal are **MUSEUM 9861, 9862, 9863, and 9864** (internal exchange, four lines).

The **TELEGRAPHIC ADDRESSES** are:

EDITOR of the **BRITISH MEDICAL JOURNAL**, *Aitiology Westcent, London.*

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate Westcent, London.*

MEDICAL SECRETARY, *Mediscera Westcent, London.*

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 4361 Central).

QUERIES AND ANSWERS.

"**PUZZLED**" asks for suggestions for treatment in the following case: A lady, over 60 years of age, with both aortic and mitral stenosis, who has had many years, months ago, which necessitated increasing doses, in order to keep the pain under, as it was not considered advisable to submit the patient to operation. At least 4 grains of morphine hypodermically are now required in the twenty-four hours to give the patient any ease. Any attempt at reducing the dose or withdrawing the drug by substituting hyoscine, etc., is followed by an alarming condition of collapse. The use of strychnine raising the blood pressure the morphine in such

Some light on this question will be found in the report of the Departmental Committee on Morphine and Heroin Addiction, of which an account appears in our present issue (p. 391).

PAGET'S DISEASE.

DR. W. JENNER (Muswell Hill, N.10) writes in reply to "M.R.C.S.": I would suggest three months' treatment at Dr. Rollier's clinics at Leyrin. If that is impracticable, treatment at home by the quartz lamp would be an alternative. There is, however, no substitute for Alpine air. If "M.R.C.S." will communicate with me I will tell him of a visit recently made to these clinics.

SCARS.

DR. D. J. JACKSON (Catford) asks for advice with regard to the treatment of a young lady vaccinated four years ago on the arm, who has now four raised scirrhous masses.

Previous answers to a similar question appeared in the **JOURNAL** in 1924, vol. ii, pp. 1086, 1144, and 1184. Both fibrolysin injections and the use of a compound resorcin ointment have been found effective in removing the fibrous tissue.

"**D. M. B.**" asks for suggestions for the effective removal of scars of boils left on the neck and face.

INCOME TAX.

Renewal of Motor Car.

"**J. A. S.**" and "**A. M. I.**"—These correspondents have raised the same question of principle. They have each replaced a car by another of superior grade, etc., but, owing to the fall in motor prices during the past few years, at a cost to themselves less than the cost of replacing the car by one of similar grade. For instance, suppose it would have cost £200 (net) to replace an "O" car by another similar car, and actually £250 was expended to replace it by a better "A" car; can the whole of the £250 be allowed so long as it does not exceed the cost of the original "O" car?

In equity we are clear that the £250 should be allowed. The renewal cost basis is an alternative method to the depreciation or gradual writing down basis, and the professional man should not be made to suffer because at one time the latter basis could not be claimed by him. From the legal standpoint the relevant provision appears to be Rule 3 (g), applicable to Cases I and II, Schedule D: "no sum shall be deducted in respect of . . . any sum employed or intended to be employed as capital

in such . . . profession." The argument of the Revenue officers concerned seems to be that because the replacement involves an improvement in the standard of the car, to that extent there is a further employment of capital. In our view there was an employment of capital when the original car was purchased, and no doubt the transaction was treated, and so long as no further sum is invested in the equipment, then any exchange of one car for another does not imply a further employment of capital, even though a superior car be obtained by the exchange. Before proceeding to a formal appeal, it might be advisable for our correspondents to place the full facts before the Board of Inland Revenue (Somer House, W.C.2) and inquire whether they cannot authorize the officers to withdraw their objection to the allowances claimed.

"**T. G.**" bought a car in 1921 for £425, and explains that a similar car can be bought now for £182 10s. (What depreciation allowance etc., can he claim?)

For 1926-27 he can claim the depreciation allowance on the written-down value of the car; for instance, on the basis of a 20 per cent. allowance he could claim £85—that is, 20 per cent. on £174, the written-down value after four years' life of the car. The renewal allowance will be the net cost of replacement less (if it has been claimed) the total depreciation allowance given against past assessments. As to the question that might arise with the Revenue authorities if an improved car is bought, see the reply to "**J. A. S.**" and "**A. M. I.**" above.

LETTERS, NOTES, ETC.

ARSENIC IN AMERICAN APPLES.

DR. T. B. WATSON (Woldingham, Surrey) writes: In your issue of February 13th (p. 297) I read the paragraph "Contamination of apples by arsenic"—those imported from abroad, I presume. As I understand that the statement is in regard to American apples, and not those from British Columbia, I am strongly of the opinion that a word to this effect should have been inserted, as, naturally, the public will not discriminate between the two unless distinctly informed. The British Columbia fruit growers have been seriously suffering for some years from very hard times, so any deleterious statement regarding imported apples generally will most certainly have a very disastrous effect on them now, just when a better prospect and a brighter outlook had, apparently, set in.

CIVILIAN MOTOR AMBULANCES.

MESSRS. MANN, EGBERTON AND CO. of Norwich designed and built last year an ambulance body for Daimler Hire Limited, London. The ambulance is a most luxurious vehicle, having the appearance of a limousine car, and rendering the conveyance of patients over long distances most comfortable. The body is mounted on a 45-h.p. Daimler chassis. The interior is paneled with light and dark mahogany. The stretcher is carried on Carter's Rastilon spring-balanced frame, mounted on a swivelling carrier. The stretcher supports a Vi-spring mattress, and nickel-plated rail runs along the unprotected side of the bed. The ambulance is fitted with two chairs, which can easily be removed; with a tip-up basin, the water being supplied from a tank fitted to the central pillar of the front compartment of the car; and with cabinets for a thermos flask, glasses, and medical accessories. Below the ambulance a sloping gangway is shown which gives easy access, when pulled out, to the wide door at the rear. The charge for so much comfort does not seem excessively working out, we understand, at about 2s. a mile, with a minimum of 2 guineas.

Of a different type is the special ambulance body built for the Sheffield Joint Hospitals Council by Messrs. E. I. Pickford, and exhibited last year at the Commercial Vehicle Show. It is designed for the transportation of both lying down and sitting patients. The equipment can be rapidly adjusted, so that the ambulance can be used either for ten sitting patients or for lying, or for two lying and five sitting patients. Moreover, the whole of the equipment can be removed in a very short time for the purpose of cleaning and disinfection. The ambulance seen very suitable for industrial districts, where many casualties may require attention at the same time, for pit accidents, or for railway disasters.

TRANSFERABLE NUMBER PLATES FOR MOTOR CARS.

DR. J. B. GARMAN (Great Barr, near Birmingham) writes to call attention to the hardship inflicted on a medical practitioner who hires a motor car or taking out a second licence during repair to his own car. He suggests that doctors should be allowed to pay for one professional transferable number plate, analogous to those issued to the motor trade, and hopes that the Medical Parliamentary Committee may interest itself in the matter.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges and of vacant resident and other appointments at hospitals will be found at pages 45, 46, 47, 53, and 51 of our advertisement columns, and advertisements as to partnerships, assistantships and locumtenencies at pages 48 and 49.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 71.

A Clinical Lecture ON DIAGNOSIS BY PYELOGRAPHY.*

(With Special Plate.)

BY

R. J. WILLAN, M.V.O., O.B.E., F.R.C.S.ENG.,

HONORARY SURGEON AND LECTURER IN SURGERY TO THE ROYAL VICTORIA INFIRMARY, NEWCASTLE-ON-TYNE.

PYELOGRAPHY (*πύελος*, the pelvis; *γραφή*, a delineation) is the radiographic outline of the hollow part of the kidney, after it has been distended by means of a ureter catheter, with a solution opaque to x rays. Its field of usefulness has been widened to such a degree that its aid must be often invoked if an exact diagnosis is to be arrived at, not only for numerous lesions of the urinary tract, but also in some obscure abdominal lesions.

Pyelography dates from 1906, when Voelcker and von Lichtenberg first demonstrated the outlines of the renal pelvis and calyces. For several years, however, the value of this diagnostic aid was unrecognized, and its popularization has been largely due to the outstanding work of W. F. Braasch of the Mayo Clinic. Perhaps more difficult than the making of a pyelogram is its interpretation, and it is for our knowledge of the interpretation that urologists are so particularly indebted to Braasch. His book on the subject is monumental.

It is now possible to diagnose by pyelography conditions such as pyelitis, pyelonephritis, hydronephrosis, renal ptosis, tubercle, and growth, together with congenital cystic kidneys and ureteral stricture. It is also valuable as a means of diagnosis in essential haematuria, in renal and ureteral calculus, and in cases of obscure extra-urinary tumour, or in which unusual shadows are seen on radiography.

The principles in the interpretation of typical conditions which it is possible to recognize by pyelography will first be given; later, brief descriptions of the history of representative clinical cases will be given, each case being illustrated by its pyelogram, and in some instances accompanied by a photograph of the pathological specimen removed at operation.

A good x-ray plant is indispensable, and the best results are obtained when the combined measures of ureter catheterization, followed by radiography, can be carried out on the same couch without moving the patient. Voelcker used a solution of collargol which gave a good shadow, but occasionally it damaged the kidneys; therefore thorium nitrate was substituted, but this sometimes had the same deleterious effect, though to a lesser degree. Sodium bromide, 25 per cent. solution, was found by Weld to give an excellent shadow; it was cheap, and did not cause any real damage. It, however, in some cases caused an acute temporary irritation of the mucous membrane of the urinary tract. I now use a 13½ per cent. solution of sodium iodide, as recommended by Cameron; I have never known it cause inconvenience, either local or general, to the patient, and it is easily sterilized.

The sterilized solution can be run into the renal pelvis either by gravity or by means of a syringe. It must be done carefully, so as to avoid overdistension with the resultant renal colic; at the same time sufficient distension must be achieved, otherwise an incompletely filled pelvis or calyces may give a misleading picture. Wherever possible ureters should be catheterized without a general anaesthetic; a pyelogram should never be made when the patient is unconscious, for to do so invites disaster by rupturing the renal pelvis from overdistension.

Anatomical Points.

To appreciate a pyelogram the gross elementary anatomy of the kidney must be borne in mind—namely, that the kidney comprises solid and hollow portions.

The *hollow part* of the kidney consists of the funnel-shaped pelvis, into which drain the cylindrical-shaped

calyces. The calyces are usually grouped into three main divisions, named upper, middle, and lower (see Fig. 15, left side). Into each main calyx drain the minor calyces, which vary in number. Although this is the usual grouping of the calyces, there are many variations of the normal which require experience for their recognition. For variations of the normal see Figs. 6, 10, and 12 (all left side), and 13 (right side).

The *solid part* of the kidney is made up of the surrounding outer cortical portion, enclosing an inner medullary part. The cortical portion does not immediately concern us. The medullary part is an aggregation of cone-shaped masses, each mass having its base towards the cortex and each apex projecting into a calyx (see Fig. 1).

The *normal position* of the kidney must be kept in mind: it roughly corresponds to the last dorsal and upper three lumbar vertebrae.

The *size* of the kidney can be approximately gauged by building an imaginary solid portion around the renal pelvis and calyces, as demonstrated on the pyelogram.

Interpretation of Pyelograms.

The interpretation of the pyelogram depends primarily on understanding (1) that the solid medullary apex projects into the outer end of the tube-shaped calyx (see Fig. 9), and (2) that if this tube-shaped calyx is distended with fluid such fluid surrounds the solid medullary apex which is projecting into that calyx (see Fig. 1).

Normal Pyelogram.—Fig. 5 is reproduced from a normal pyelogram. If the individual calyces are observed they will be seen to have cup-shaped outer ends; these show that the sodium iodide has surrounded the normally projecting apex of the solid renal medullary cone. Normal pyelograms will be seen also in Figs. 7, 10, and 13 (all left side).

Pyelonephritis and Hydronephrosis.—Compare the diagrams (Figs. 1 and 2). Fig. 4 is from an abnormal pyelogram, where there has been absorption of the solid apex of the renal pyramids. It will be seen that the outer ends of the calyces (instead of being cup-shaped as in the normal) are “knobbed.” This alteration is due to the absence of a projecting solid apex (see Fig. 2). Such rounding is indicative of inflammation, and indicates pyelonephritis with destruction of some portion of the solid renal tissue; an advanced stage of this “knobbing” is seen in hydronephrosis (see Fig. 6).

Ptosis of Kidneys.—Patients suffering from renal ptosis commonly complain of vague, long-standing abdominal pains. In these chronic cases a combination of the separate results of pyelography and a barium enema will make the diagnosis of general visceroptosis. Kinks and twists in the ureter are common in renal ptosis (see Fig. 13). Their discovery by pyelography may or may not be of moment; it entirely depends on the presence of “cupping” or “knobbing” in the minor calyces. “Cupping” indicates medical treatment, for there is no back pressure; “knobbing” means back pressure due to obstruction, and nephroproxy may be required to straighten out the ureter and ensure a free onward flow of the urine.

Congenital Cystic Kidneys.—In a congenital cystic kidney there is a general enlargement of the organ, which is shared by the hollow part—that is, the pelvis and calyces (see Fig. 5). The knowledge is used in diagnosing this condition by pyelography. The disease is always bilateral, but one kidney is in a more advanced stage of disease than the other—that is, one is usually the larger. When only one enlarged kidney is felt, it might be mistaken for growth or hydronephrosis; and the surgical removal of a congenital cystic kidney is usually fatal from uraemia. Recently a patient was sent to me with two enormous tumours occupying the whole abdomen. It was thought to be possibly a case of malignant ovarian cysts, and operation was desired. Fortunately pyelography provided a definite diagnosis of congenital cystic kidneys, and a useless risky laparotomy was avoided.

Tuberculosis.—The characteristic tendency of tubercle anywhere in the body is for it to undergo caseation and disintegration, when the contents are discharged, thus leaving a cavity. In the case of a disintegrating kidney focus the tuberculous debris escapes into the nearest calyx and is voided down the ureter with the urine. Therefore,

* Given to the students at the Royal Victoria Infirmary, Newcastle-on-Tyne, on December 9th, 1925.

when making a pyelogram, the sodium iodide injected through the ureteral catheter escapes from the calyx into the disintegrated tuberculous cavity situated in the solid part of the kidney; the sodium iodide has escaped the normal confines of the hollow calyx and has "run amok" in the solid part of the kidney. A tuberculous pyelogram shows, therefore, a blurring in connexion with one or more calyces, according to the extent of the tuberculous disintegration (see Fig. 8).

Hypernephroma.—A hypernephroma usually invades one or other pole of the kidney when it involves at least one main calyx. Depending on the extent of the lesion, the resultant pyelogram may show one or two normal calyces only, while the third main calyx is absent; and the pyelogram has the appearance as if the calyx had been amputated (see Fig. 10).

Essential Haematuria.—From time to time a surgeon is asked to see a case of painless haematuria. Where the physical signs, apart from the non-purulent haematuria, are negative, the case may be one of considerable anxiety. Cystoscopy may disclose a normal bladder, also evidence from which kidney the patient is bleeding. Among other things, the bleeding may proceed from a malignant kidney, or it may be a case of essential haematuria. The fact that the patient is bleeding from a kidney does not necessarily demand exploration or nephrectomy, for pyelography will help in a diagnosis. If the urinary tract x-ray shadows and pyelogram are normal; if the ureteral catheter end is in the renal pelvis of the affected side and the urine withdrawn contains blood; if the blood pressure is normal; if the urine is free from pus and renal casts; and if the painless haematuria has been continuing for some time, the diagnosis of essential haematuria is probably correct. Such a diagnosis can only be arrived at by pyelography. If the pyelogram is at all suspicious it should be repeated after an interval, when a careful comparison of the two pictures should be made.

Urinary Calculus.—A uric acid calculus which may not throw an x-ray shadow will sometimes do so after distending the renal pelvis and allowing part of the opaque solution to drain away; some of the solution may adhere to the calculus and cast a shadow.

Shadows near the Line of the Ureter.—Extraureteral shadows can be differentiated by ureterography during pyelography, owing to the presence of some sodium iodide in the lumen of the ureter.

ILLUSTRATIVE CLINICAL CASES.

CASE I.—*Pyelonephritis.*

M. W., aged 30, had right flank pain for ten years and occasionally it was accompanied by vomiting. Nine months earlier the appendix had been removed without giving relief to symptoms. Physical examination showed a tender spot behind the right kidney and the urine contained pus cells microscopically.

Pyelography (see Fig. 4) showed "knobbing" of the calyces of the right kidney without dilatation of the pelvis or calyces, enabling a diagnosis of chronic pyelonephritis to be made. A bacteriological examination of the urine gave a pure culture of staphylococcus, and vaccine treatment was recommended.

CASE II.—*Hydronephrosis.*

Annie L., aged 15, for some years had attacks of right-sided renal colic, associated with increased frequency of micturition. On one occasion only had there been haematuria. Her urine contained pus and albumin. There was tenderness behind the right kidney, but neither kidney was palpable. Nothing abnormal was disclosed in the rest of the abdomen or on rectal examination.

The double pyelogram (see Fig. 6) shows a normal left renal pelvis and calyces, and an enlargement of this (see Fig. 3) is used as my example of a normal pyelogram. It also shows marked hydronephrosis on the right side, both pelvis and calyces being involved. If it is carefully observed the grouping into the three typical main calyces can be seen—namely, upper, middle, and lower; further, there is an advanced degree of "knobbing" of the minor calyces, due to the atrophy of the solid part of the renal tissue. This is a further stage of pyelonephritis (see Fig. 4). If the photograph of the cut surface of the removed kidney (see Fig. 7) be compared with the pyelogram the points mentioned can be confirmed—namely, the dilatation of the pelvis and calyces; the arrangement of the three main calyces (each marked by a short piece of wire); and the marked thinning of the solid part of the renal tissue, with the disappearance of the apex of all renal pyramids. The hydronephrosis was due to a stricture at the outlet of the renal pelvis. The patient made a good recovery after nephrectomy.

CASE III.—*Congenital Cystic Kidneys.*

H. S., male, aged 23, for some months had been suffering from typical attacks of right-sided renal colic. There had been polyuria

with slight haematuria. Recently he had had rigors, intense thirst, frontal headaches on awakening in the morning, and lost weight. On examination both kidneys were enlarged, more and tuberoso, especially the left-sided one. The urine was of specific gravity and contained pus.

Pyelography (see Fig. 5) showed general uniform enlargement of the pelvis and calyces of both kidneys, particularly the right. The clear definition of the pelvis and calyces outlines exclude tuberculosis, growth, and hydronephrosis, and confirmed diagnosis of congenital cystic kidneys.

CASE IV.—*Example of Tuberculous Kidney.*

Mary K., aged 20, for some years had occasional pain below the left kidney. Six months prior to admission she began to have mild attacks of renal colic associated with strangury, but with haematuria on one occasion only. She had lost weight and was troubled with night sweats. Examination disclosed tenderness and rigidity over the left kidney, but neither kidney could be palpated. On vaginal examination the thickened terminal portion of the left ureter could be felt in the left lateral fornix. Cystoscopy showed ulceration around the left ureteric orifice, which masked the opening so much that its catheterization was a matter of considerable difficulty.

Pyelography showed a typical tuberculous left kidney: a definite diagnosis of tubercle limited to the upper half of the kidney was made, and a nephrectomy was done on February 12th, 1925. The patient made an uninterrupted recovery. The pyelogram (see Fig. 8) shows a normal main lower calyx; the upper and middle calyces, however, have lost their definition and have a "huffy" appearance. This made possible the diagnosis of tubercle limited to the upper half of the kidney. On reference to the cut surface of the removed specimen (see Fig. 9) the tuberculous ulceration and cavitation is seen in the upper half of the kidney and is particularly in communication with the upper main calyx. The lower normal main calyx can be seen, and into it projects the normal apex of a medullary cone.

CASE V.—*Example of Malignant Growth.*

T. G., aged 59, male. Six weeks before admission there was profuse painless haematuria immediately after having lifted a heavy weight; there were no clots. This painless bleeding was the only symptom; it was intermittent, and occurred on six occasions prior to admission. Except for this the patient was in excellent health in every way. On admission his urine contained bright red blood, no other abnormal physical sign could be elicited, but cystoscopy showed blood trickling out of the right ureteric orifice.

Pyelography disclosed a normal left-sided pyelogram with an abnormal right-sided one. A definite diagnosis of malignant right kidney was made and a nephrectomy was done. The patient made an uninterrupted recovery and has now returned to his work as a coal miner. The abnormal pyelogram (see Fig. 10) is hooked at its upper end with a large oval shadow at the extremity, the oval shadow corresponding to a calyx. The absence of the other calyces (they had been cut off) with the renal distortion sufficed to convince me that I was dealing with a hypernephroma which had destroyed at least half of the kidney. The cut surface of the specimen removed at operation (see Fig. 11) shows that the lower two-thirds of the kidney has been replaced by growth, and that the dilated renal pelvis was also occupied by malignant growth. The injected sodium iodide had tracked up between the growth and the upper margin of the pelvis, to reach the normal calyx in the upper pole of the kidney.

Microscopically, Professor Stuart McDonald reports: "This is typical hypernephroma, portions of which are distinctly adenomatous. There is extensive necrosis of the tumour growth, which is of definite infiltrating type."

CASE VI.—*Example of Abdominal Tumour.*

Mrs. W., aged 42, was sent to me for pain in her left side which limited full inspiration; she had had haematuria of slight degree, but without frequency. A large tumour occupied her left ilio-costal space, which was justifiably taken to be an enlarged kidney. Her bowels were regular and she was not losing weight. A large tumour could be felt in the upper part of the space; it was dull on percussion, and this was posteriorly to the middle line. The urine contained pus and blood; the blood examination showed a lymphocyte leucocytosis. Cystoscopy revealed an acute cystitis.

Pyelography (see Fig. 12) demonstrated that the left kidney had been displaced downwards so that the hilum of the organ, instead of pointing medially, was pointing towards the iliac fossa. The upper part of the ureter forms an acute angle with the lower portion. If an imaginary line be drawn above the shadow thrown by the renal pelvis and upper part of the ureter, the size of the splenic tumour can be gauged.

CASE VII.—*Ureter Kink.*

Janet R., aged 30, complained of haematuria on a single occasion, followed by acute pain behind the right kidney, but without increased frequency of micturition. When seen there were no abnormal physical signs. Cystoscopy showed a normal bladder.

Pyelography showed a psoed kidney with a knot in the upper part of the ureter (see Fig. 13). The renal pelvis and calyces were normal, which is a definite indication that there was no obstruction to the onward flow of urine. The haematuria remained unaccounted for. A year later the patient was well and had had no return of her symptoms.

Some of the pyelograms reproduced with this paper were made in a private hospital. I am indebted for the others to the physician in charge of the radiography department of the Royal Victoria Infirmary, Newcastle-on-Tyne.

FIG. 1.—Diagram of section of normal kidney. Note the conical apex projecting into the calyx, producing the normal "cupping" of the calyx in a pyelogram.

FIG. 2.—Diagram representing pyelonephritis. Note the disappearance of the conical apex, thereby producing "knobbing" of the calyx in a pyelogram.

FIG. 3.—Normal Pyelogram. To illustrate the "cupping" on the minor calyces.

FIG. 4.—Pyelonephritis Pyelogram. Shows the "knobbing" of the minor calyces due to absorption of the renal pyramid apices.

FIG. 5.—Congenital Cystic Kidneys (double). Note each renal pelvis and each calyx are proportionately enlarged. The right kidney is the larger tumour. The size of each kidney can be gauged by filling in an imaginary solid portion around the pyelogram.

FIG. 6.—Hydronephrotic Kidney. See dilatation of the three main calyces, and calyces. Fig. 7 is the specimen.

FIG. 7.—Hydronephrotic Kidney. See thinning of the solid pyramid apices; stricture of the p calyces are each indicated by pieces of wire. (cf. fig. 6.)

FIG. 8.—Tuberculous Kidney Pyelogram. Note lack of all definition of the upper and middle main calyces; the lower main calyx is normal. Fig. 9 is the specimen relating to the pyelogram.

FIG. 9.—Tuberculous Kidney. Note tuberculous ulceration and cavitation in upper half of the kidney, also lack of outline of the upper and middle calyces. Note also normal lower main calyx, with a pyramid apex projecting into a calyx. (Cf. Fig. 8.)

FIG. 10.—Malignant Kidney Pyelogram. Note normal left pyelogram with filling defect right side, where only one main calyx can be recognized, and that indistinctly. Fig. 11 relates to the removed specimen.

FIG. 11.—Malignant Kidney Section. The upper main calyx is the only one to be seen; the others have been "amputated" by growth. Note growth in renal pelvis, also in lower two-thirds of the kidney. (Cf. Fig. 10.)

FIG. 12.—Kidney displaced by Splenic Tumour. There is an accumulation of the ureter, the horizontal part of which, together with the kidney, is displaced downwards by a splenic tumour. The convexity of the kidney is displaced towards the left iliac fossa.

FIG. 13.—Ureter Knot. Shows a knot in the upper end of the ureter in a ptosed kidney. There is no "knobbing" of the calyces—that is, there is no obstruction to the urine flow.

SPLENIC ANAEMIA OF YOUNG CHILDREN TREATED BY SPLENECTOMY.

BY

HUGH T. ASHBY, M.D., CANTAB., F.R.C.P.,

PHYSICIAN,

AND

A. H. SOUTHAM, M.D., M.Ch. Oxon., F.R.C.S. Eng.,

ASSISTANT SURGEON,

THE ROYAL MANCHESTER CHILDREN'S HOSPITAL.

We wish to draw attention to the possibility of treating cases of splenic anaemia in young children by the removal of the spleen, and to record three cases treated by splenectomy with successful results.

Splenic anaemia of young children, or, as it is sometimes called, von Jaksch's anaemia, is a disease which occurs during the first three years of life and is characterized by marked anaemia, great enlargement of the spleen, and much general debility. The disease is essentially chronic and continues for many months, or even years. The prognosis in advanced cases is unfavourable, though some do undoubtedly improve and recover after prolonged treatment. Many are carried off by an intercurrent disease, such as bronchopneumonia, to which they are very liable.

Splenic anaemia of young children has no relation to the splenic anaemia of adults, and it is probably a disease *sui generis*, though the exact cause is not yet known. Some observers are of opinion that it is an extreme form of rickets with anaemia. Most cases of splenic anaemia of young children do show some signs of rickets, but this is not always well marked. The disease may occur in twins; of this we have seen two instances.

The symptoms are insidious, accompanied by indigestion, and it is impossible to say exactly when the disease actually begins, but the child gradually becomes pale and wasted and the enlarged spleen is then detected. The pallor is marked and the colour is often pale lemon. The red blood corpuscles are much diminished in number in a severe case and may fall to just over 1,000,000 per c.mm.; they vary in size and shape and there are many nucleated red corpuscles; the haemoglobin is much reduced. There is a moderate increase in the white cells, with a preponderance of lymphocytes and a few myelocytes. In a severe case the spleen reaches down to the pelvis and stretches across the middle line; it is hard and the notch is well felt. The liver is increased in size. The lymphatic glands are not enlarged. There is generally pyrexia, mild but prolonged.

TREATMENT.

The treatment is on general lines, with proper feeding combined with arsenic and iron. X-ray treatment has been of little value in our hands and has seldom influenced the course of the disease or the size of the spleen. Owing to the uncertain results obtained with medical treatment in advanced cases, and the fact that these cases often do not improve but rather tend to grow worse, we decided to try the effect of removal of the spleen, and have performed this operation on three occasions during the past year. Splenectomy was only undertaken after medical treatment had failed to give relief and after careful consideration.

It seems that the spleen in these cases is a diseased organ, and that the child will be better without it if it can be removed with a reasonable degree of safety. Splenectomy is now recognized as a definite surgical procedure, and the operation has in recent years largely increased its scope. Until fairly recently surgical removal of the spleen was limited to cases of injury, torsion, or where it was the seat of a new growth; now, however, it is performed in certain cases of anaemia, cirrhosis, and acholuric jaundice, and appears to give excellent results in suitable cases.

It is well established that the spleen is not essential for the carrying on of life, and little harm seems to come to the

individual after its removal. In those cases of splenomegaly the etiology of which is at present unknown, splenectomy appears to be a procedure of distinct clinical value. Before undertaking it every effort must be made by the careful preparation of the patient to reduce the risk of the operation as far as possible. Owing to the extreme degree of anaemia from which these patients may be suffering, their condition can be much improved and the blood count correspondingly raised by preliminary transfusions of blood. In addition, when the spleen is considerably enlarged, the re-transfusion of the blood it contains, after the spleen has been removed, is a procedure worthy of consideration. The blood so obtained is unaltered in character, and there appears to be little risk in this simple method of auto-infusion. Further, the application of a massive dose of x rays over the spleen shortly before operation, as advised by Moynihan,¹ may lead to shrinkage of the organ and render the operation more simple to carry out. In one of our cases the reduction in the size of the spleen under the influence of x rays was marked.

In performing splenectomy a left-sided paramedian incision, with outward displacement of the rectus muscle, was used, and this gave ready access to the organ. Adhesions were troublesome in two of the cases, but with careful clamping the spleen was removed without difficulty and with very little haemorrhage. The absence of post-operative shock in such young children was very noticeable and was largely due to the careful preliminary treatment of the patients. The following are the notes of the cases.

CASE I.

A boy, aged 1 year and 11 months, was sent to the hospital from an infant welfare clinic on account of anaemia. The child had been breast-fed for the normal time, but since the age of 1 year he had not been well. For the five months previous to coming to hospital there had been difficulty with his feeding, some vomiting, and a marked loss of weight. There had been no cough, no abdominal pain, and the bowels were regular. The spleen was very large, reaching well down into the pelvis and across the middle line of the abdomen. It was hard and the notch was easily palpated. The child was of a pale lemon colour and the blood count was:

Red blood corpuscles	1,360,000
White blood corpuscles	31,200
Polymorphonuclears...	26 per cent.
Lymphocytes	71 "
Haemoglobin	30 "

A fair number of nucleated red corpuscles and a few myelocytes were seen. The blood platelets were increased. The Wassermann reaction was negative and there were no haemorrhages.

He was admitted to hospital on April 22nd, 1925, where he was kept for a month. He was properly dieted, had a course of arsenic and iron, and also x-ray treatment to the spleen. He improved only slightly and was sent home, where the same treatment was continued. He became rather worse, and was readmitted to hospital on June 17th, 1925. The spleen was causing trouble because of its great bulk, and the child could hardly bend forward. He seemed to us as likely not to recover, and it was decided to remove the spleen. The blood count at this time was practically the same as when admitted to hospital on the first occasion. He was slightly rickety.

On July 2nd, as the father proved to be a suitable donor, the child was given a transfusion of 40 c.cm. of blood into the external jugular vein. Blood examination a week later showed that the red blood corpuscles numbered 1,420,000 per cubic millimetre. Two subsequent transfusions from the father of 60 c.cm. each were given on July 11th and July 17th, and the blood count showed that the red cells had risen to two and a half millions. On July 19th he received a massive dose of x rays over the enlarged spleen.

On July 20th splenectomy was carried out. The spleen, which appeared to occupy about half the abdomen, was easily delivered and adhesions caused little trouble. The pedicle was divided between clamps and the organ handed to an assistant. By squeezing the organ 40 c.cm. of blood were obtained from the splenic vessels, and this was run into citrate solution and returned into the external jugular vein of the child. There was no free fluid in the abdominal cavity, and the liver, which was slightly enlarged, appeared smooth and normal in colour and consistence.

The spleen, after removal, weighed 540 grams (18 oz.), and it was then devoid of blood. The length was 15 cm. and the width 10 cm. It had preserved its normal form; it was fairly firm and

OSTEOMALACIA IN KASHMIR.

BY

KATHLEEN VAUGHAN, M.B.LOND.,

LATE SUPERINTENDENT, ZENANA STATE HOSPITAL, SRINAGAR.

OSTEOMALACIA is extremely common in Kashmir. I was for nearly three years medical superintendent of the Maharajah's Zenana Hospital in Srinagar, the chief city, and out of twenty-nine Caesarean sections performed by me during my first year there at least twenty-five were due to pelvic deformity caused by osteomalacia. Of the total 120 midwifery cases admitted to hospital in the year none presented themselves until they had had all the advice available at home, and, with the exception of two, after rupture of the membranes. The number of Caesarean operations increases yearly in Srinagar as the women gain confidence in the hospitals, and their relations take a larger proportion of them for relief rather than allow them to die at home, which was formerly their fate.

Almost all Kashmiri women who have borne children are affected in some degree, with the exception of the *manji* (boatman) class. Dr. Ernest Neve, who has worked in Kashmir for over twenty-five years, tells me that he does not remember having seen a case of osteomalacia among the boat women, and I too have never seen a case among them. These women live in the open air on the large boats used for carrying rice, wood, etc., on the great Kashmir highway, the Jhelum river; and besides the men, women, and children, fowls, goats, and sometimes a cow with her calf, are on board. These women work hard, and feed with the men. They are too poor to cook their food much, and eat raw cucumber, tomatoes, etc., with their rice, which they husk by hand. They pole and paddle the boats like the men, and are out in all weathers. Their milk supply is provided by their goat or cow, and one may be fairly certain it is not boiled, but consumed as soon as drawn. The disease is unknown among men in any part of the world, and Kashmir is no exception.

The ordinary Kashmiri woman who lives on land, especially the city dwellers, have the disease—sometimes slightly, when there is tenderness of the pelvic bones and the antero-posterior curve of the sacrum is exaggerated, or so acutely that the sufferers can only crawl by means of their arms and legs, the legs being flexed at the knees and the knees drawn up to the shoulders. The worst cases are seen in the houses of the wealthy, who keep their women in seclusion, and among those of the poorer classes who do the same.

There is a marked seasonal incidence; the disease is worse in winter and early spring, during and after confinement to the house in the cold weather, and improves markedly during summer and autumn. A common history is that of confinement to the house at 8 or 9 years of age, marriage at 10 or 11, menstruation at 12 or 13, and close confinement in the husband's house until after the first child is born; in the most high-class families the women hardly leave the house till they die. The ordinary woman has more freedom, and when she has borne two or three children she goes out with other women.

Anaemia and debility characterize pregnancy, with vague pains in the ribs, back, and legs, increasing until walking is difficult or impossible at term. The earliest pains complained of are in the lower ribs, about the centre of the bone, and tenderness on vaginal examination may be the first complaint to arouse suspicion of the disease; the pain on pressure is found to be at some spot on the bony wall, not at the symphysis. Backache is a constant complaint, as it is with many pregnant women, but the typical pelvic deformity eventually produced in an acute case which has been going on for years is the tri-radiate pelvis, the pubic bones being pressed together and giving the familiar rostrated appearance—the acetabula pressed in towards one another, the sacrum tilted forward, and the coccyx bent forward: the sacral curve is then more concave than normal, and the foetus at full term may rest on a bony

shelf formed by the crumpled-up bones of the maternal pelvis. The following are sample measurements:

Mohammedan, aged 30; purdah, married two years before menstruation began: Interspino 16 cm., intercrystal 19 cm., intertrochanteric 18 cm., external conjugate 15 cm., bi-ischial 5 cm.

A woman aged 28; purdah on marriage two years before menstruation began; her mother also suffered from osteomalacia: Interspino 17½ cm., intercrystal 22 cm., intertrochanteric 23½ cm., external conjugate 17 cm., bi-ischial 4 cm.

In a few of our cases it was difficult, if not impossible, to reach the os or rupture the membranes; in others the pubic rami were so close together that a finger could with difficulty be inserted sideways. Tetany is a common accompaniment of osteomalacia; women are brought to the hospital with their thumbs flexed in the palms of their hands and the whole hand flexed at the wrist. It is not a hysterical manifestation, as experience shows its close connexion with osteomalacia and probably with thyroid and parathyroid deficiency. In many of these cases the thyroid is smaller than normal, and the neck seems wasted on inspection.

Toothache is a common complaint, and pyorrhoea is often present; but the most obvious symptoms are the pains in the bones, in the ribs, pelvis, and the shafts of the long bones, especially the tibia and ulna, which are tender on pressure about the centre. No tenderness or change is to be observed at the joints. The epiphyseal lines seem to me quite unaffected, thus differentiating the condition from rickets.

There may be improvement after confinement, and when lactation ceases. Lactation only ceases when the child dies, otherwise it is continued for from two to four years, and the osteomalacia becomes more acute when the woman again becomes pregnant. Many when pregnant are suckling one or two previous children. A man in Srinagar once said to me: "The reason I am so small is that when I was a baby my elder brother took all my mother's milk because he was a strong boy; and then my mother had another baby and gave her milk to him, so I got none"—a common history.

The acute pains are usually better after delivery, but recur in the second and later pregnancies. The third confinement results in more crippling, and by the fifth month the patient cannot sit or stand or walk without severe pain. She gets up from the ground or from a chair by pressing her hands on her legs as she straightens them and the feet are turned in to keep the balance. This is the earliest symptom noticeable in the street in walking behind such a woman, who looks as if she was going to fall over her big toes, and the gait has a well marked waddling character. Many suffer from phthisis and tuberculous glands, and many of the men of the families in which there is osteomalacia suffer from tuberculosis. It is too constant a relationship to be mere chance.

Anaemia is always present, and unfortunately is admired, as a fair complexion is considered a sign of being well bred. The Kashmiri of pure Aryan parentage is fair, and some of the men carry umbrellas to guard their complexions from the sun. The pale hue so much sought after is increased by the seclusion of the women, not only from the outside world but from sun and air. The better-class women when they go out wear, from the age of 10, a "burka"—a cloak covering the head and body, with two lattice-work holes for the eyes.

Palpitation and breathlessness, the usual accompaniments of anaemia, are present, and a dilated heart is not uncommon. In a well marked case the pulse is always rapid, and may rise to 120 or 140 on the least exertion.

The temperature is not raised. Oral sepsis, indigestion, and intestinal worms are common.

Some apparently impossible midwifery cases terminate spontaneously after several days in labour—provided, of course, the deformity is not such as to prevent the head engaging in the superior strait of the pelvis; the pressure of the head may be sufficient to make the softened bones yield, but as the woman gets older the bones ossify in faulty positions and the crumpled pelvis becomes unyielding.

Many deaths take place in childbirth owing to conditions consequent upon osteomalacia, and as skilled

assistance is not available mother and child are often lost. The native midwife, who has no training but tradition (the trade is hereditary), performs a rough craniotomy with the sharp end of a spindle, removes the infant's brains, places a loop of string round the neck, and extracts. In a difficult case she may pierce the mother's uterus, and the mother frequently dies of septicaemia. A native midwife will "clean" her hands before making an examination by rubbing them on the mud floor. She frequently completes her attentions to the patient by rubbing salt or mustard oil into the lacerated vagina. Atresia of the vagina caused by such measures is fairly common. A natural cure of the pains and softness of the bones occurs at the menopause.

One of the most remarkable things where Caesarean section is done for these women is the size and healthiness of the child. The women are thin, anaemic, and deformed; their offspring at birth are often extremely fine, healthy, heavy specimens, and later show no sign of rickets. All the mothers suckle their offspring. Rickets is not common in Kashmir. The few cases I have seen were in female children who had lost their mothers in infancy, belonged to wealthy Kashmiri families, and had been kept indoors with the women. Usually even infants go out, and male infants are taken out by the men and boys to show to their friends when very young. A girl child is never made so much of.

There are three indigenous Kashmiri cures for "trouble in the bones": (1) a special clay called baramulla earth; (2) pills made of fish liver; (3) rubbing with mustard oil and exposing to sunlight.

1. Baramulla earth is a greyish-white fire-clay used for making fireplaces in wooden boats, and for portable fire-pots on which to cook food. A lump of this earth taken from a patient with osteomalacia, who ate pieces of it, was analysed for me by the Clinical Research Association, which reported that it was a ferruginous clay containing a fairly high percentage of calcium phosphate (calcium phosphate 16.2 per cent., ferric oxide 11.8 per cent., hydrated aluminium silicate (in clay) 71.2 per cent., and undetermined residue 0.8 per cent.). Sulphates were present to a very small extent. The radio-activity of the sample was not more than is usually found in any natural earth; arsenic and similar metals were not detected.

2. The fish-liver pills are sold by a Panditani (Hindu woman) living at the city fish market. She makes them herself. The analogy with cod-liver oil is interesting.

3. The mustard oil and sunlight cure is chiefly used by the men for their rheumatic pains.

At the Zenana Hospital we prescribed cod-liver oil and phosphorus oil in 3-minim doses, and considered it did good. Calcium lactate in 10-grain doses seemed to slow the heart and relieve the pains in acute cases. Hypodermic injections of sodium morrhuate seemed to give good results, but we found that the one patient cured had been sitting in the sun all day in order to get tea from the kitchen. I am inclined to think the same of cases said to improve when admitted to hospital, as the light in the wards is better than anything they have at home. Out-patients given cod-liver oil and ordered to go out on the lake in open boats improved rapidly.

Good results have been reported from excision or resection of the ovaries. It must, however, be remembered that once a woman ceases to menstruate she is no longer guarded with the same care, and will have more chance to go out in the sun. This may account for the marked improvement at the menopause seen in all cases.

Various theories have been put forward as regards this disease and its frequency in Kashmir.

Diets.

The richer classes cook all their food. The milk is boiled and reboiled. The city dwellers who keep their own cows have them in dark stables or in the courtyard and send them out daily to graze. In some cases they are fed on dry food and rarely go out. Sheep and goat's milk is used, generally when prescribed as medicine by the Kashmiri practitioner. Vegetable oil, either mustard or sesamum, is used for cooking. The oil is heated to boiling point first. The women eat no raw vegetable or fruit; they think anything uncooked un-

wholesome, and in a place decimated by cholera every few years it probably is. The rich eat rice husked by machinery, which removes the pink pericarp and the germ. The bran which is thus produced is given to the cattle, and is, of course, rich in phosphates. The women eat after the men, and therefore get less meat and milk, both considered luxuries, but otherwise their diet is the same as that of their menfolk.

The drinking water in the city comes from two sources—the river Jhelum and the tap water. The tap supply is often contaminated by the breaking of the lids of the wooden troughs which convey it to the city from a valley three or four miles away. When broken the nearest inhabitants drink and wash themselves at the break, so that last year warning had to be given to consumers that the water should be boiled before use as it was probably infected with cholera. Both rich and poor drink water, but tea is the favourite beverage for all. The better kinds come from Tibet in bricks, from which shavings are made and boiled up with salt and spices.

The natural supply from the river is preferred by the most religious, as the water of the Jhelum is sacred. The river is also the natural sewer of the town. One encounters corpses in it—from those of rats and fowls to those of drowned sheep and cattle, bodies of unwanted babies, and of persons drowned by accident. In addition to this the Hindus attend to the calls of Nature, wash themselves, and drink of its waters at the steps leading to it, and the Mohammedans have boxes in the stream for washing and sanitary needs. Persons may thus be seen drinking water from the river a yard or two lower down from those passing their urine and faeces into the same stream. The water of the river is considered so sacred that it cannot be defiled. It can hardly be matter for surprise that everyone suffers from intestinal worms. Large round white ones are the commonest, and their leaving the body is often a sign of the impending death of a patient, as a house-surgeon with long Indian experience once pointed out to me.

Social Customs.

Purdah, which means a curtain, is used of the system which ensures the seclusion of the woman from all men except her husband and her brothers. It varies in strictness, and is much less strict in Kashmir than in India. In Kashmir it really only affects the women of marriageable and child-bearing age. Among the better classes they are more or less confined to the house.

Girls of 8 are not allowed out alone, and if brought to hospital are often closely veiled. The Hindus, who in theory do not observe this custom, do so in practice. The young girls from 8 or 10 to 15 rarely go out until married, and then not till after the birth of one or two children. Marriage takes place before puberty in many cases, because in order to ensure early marriage the younger the bride the less are the fees to the priests. One of the greatest sins a father can commit is not to have married his daughter at puberty. After marriage she is confined to her husband's house, and her food and happiness depend entirely upon her mother-in-law, who often keeps her short of food, from an idea that she will have an easier confinement if the foetus is kept small by spare diet. It has been pointed out by other observers that much tuberculosis originates in these girls during the first year of married life owing to these miserable conditions.

At childbirth the woman is confined in a dark unventilated room, often with no window at all, no fireplace, but a charcoal brazier or the fire basket. Forty days is not an uncommon time for the young mother to be in this unventilated place, and she emerges weak and ill. Osteomalacia usually begins with the first pregnancy or soon after marriage.

Hereditry.—Mothers with old osteomalacia will bring daughters or daughters-in-law to hospital, and are anxious to say that the disease is *not* in their family, but is hereditary in some other family with whom marriages have been made. One finds they belong to one social caste whose rules require seclusion of girls from 8 or 10 years of age until after marriage and when they have borne several children.

Climatic Conditions.

Kashmir lies between 32° and 36° latitude, and is roughly at the same distance from the equator as Southern Spain or Morocco. The city of Srinagar lies in the valley through which the River Jhelum flows, and the town is built on each side of the river. The valley lies at an altitude of 5,000 feet. The hills round this valley are 7,000 or 8,000 feet in height; further away are hills of 12,000 to 13,000 feet, and still higher peaks overtop these in the distance.

All English flowers and fruit grow well. The temperature may rise to 90° or over in the hottest days of July and August; and again in winter the thermometer falls 10° and more below zero; yet on the whole it is a temperate and equable climate for eight months of the year. In the winter months osteomalacia becomes much worse. Wood is the fuel burnt, and during the four winter months a thick pall of fog and smoke hangs over the city in the early morning and evening.

The streets leading from the river are narrow and tortuous, and the houses, which are of wood, are high and built round small courtyards, where in the winter the sun never shines. Nor does it reach the ground of many of the streets where the aspect faces north. Icicles ten feet and more in length hang for weeks in such places from the roof, and snow to a depth of four or five feet lies in the streets. The roofs have to be cleared of snow or they would give way under the weight; men shovel it off, and it lies in the streets until spring comes. Owing to reflection there is some slight improvement in the light in the dwellings when the snow comes.

The women wear but one garment and go out in the winter as little as possible. They live in the lowest rooms of the high wooden houses in the winter, so as to be on the same floor as the water supply and the fire. The ground floor is the warmest. The windows are sometimes less than half a yard square, and protected against thieves by being near the ceiling and closed by wooden lattice-work. All windows are so made, but on the upper floors are larger. In winter they are covered with oiled paper to keep out the cold. The minimum of available light is thus admitted, and some rooms, specially liked for warmth, have no windows at all.

That the light supply is sufficient for health in all ordinary life is proved by the rarity of rickets and the healthiness of the boat women and the country women working in the fields, but a degree of seclusion which would have little effect on the plains of India produces osteomalacia in Kashmir. A photographer who lived for many years in Kashmir said that he always gave twice the exposure he would in England to get a good result in Kashmir, which looks as if the actinic rays might be deficient. Most of the oblique rays of the sun in mid-winter are cut off by the mountains encircling the valley.

Sunlight alone can cure the disease, and cod-liver oil without sunshine is of very little use. The seasonal incidence above described points to the same cause—absence of sunlight. In spring and summer the women go out and improve in health. The disease only occurs in those deprived of sunlight, and one meets women walking about who have evidently had the disease, and who will tell you they were shut up as young women, but on the death of the husband were free to go out. One woman told me she only began to suffer in her later confinements when her husband had moved from a house facing an open space to the crowded quarters of the city. The fact that the men of the families where the women have osteomalacia are so often tuberculous points to the same thing.

Reports from places in India where cases of osteomalacia occur would indicate lack of sunlight as the cause.

At Islamabad; higher up the valley than Srinagar, the doctor tells me that wherever she goes she sees cases, especially among the wives of priests, shopkeepers, and butchers—all men having some means and able to keep their young wives in seclusion during their early married life. At Ladakh, 11,000 feet, with long cold winters, it is unknown, except for one case in a Kashmiri woman. The women there go out freely. At Peshawar among the Afghan women, who go out freely and live an open-air life, none were known; the only cases reported were in Hindu shopkeepers' wives, who married young and were kept

in purdah. In Lahore the disease is uncommon; the worst cases occur among those who seclude their women and are rich enough to have glass windows, sometimes made so that they cannot be opened.

The most instructive notes come from Bombay, where the Parsee women are completely free from it, and yet the women of the weaver class have it, and were they not recruited from the outside country villages would die out in a generation. A Parsee doctor tells me that out of 25,000 deliveries he did not encounter one case of osteomalacia among Parsees. They have great freedom, and do not marry until about 20 or 22. The weaver class, on the other hand, living in the same town are almost all affected. The superintendent of the Cama hospital tells me they suspect osteomalacia in every weaver woman coming for her confinement. These women live in buildings eight stories high. The loom is on the ground floor in the room facing the street, because all available light is needed for the work, and the women live in dark rooms behind that; the mortality rate is 678 per 1,000 infants under 1 year.

In Chamba, in the Himalayas, the village women do not suffer, but in the hill town there is "hardly any sunlight" in their houses, and those in purdah, the richer women, suffer badly. In Hyderabad the disease is very rare, but cases are known in Hindu women, who eat fuller's earth to cure it.

I also have some notes of the occurrence of the disease in cows in places as distant from one another as Norway, New Zealand, and Australia. I have never seen a case in cattle in Kashmir, but there the cows living in the city are turned out to pick up any garbage they can find in the streets. They thus get any sunlight and air available. In Norway fractures of the bones of affected cattle were reported. Its occurrence in male animals, and its appearance after drought when artificial dry feeding had to be resorted to; the absence of the disease in cows at the sea where they consume fish, and in the extreme north where there is darkness for several months in winter, are all points of interest. Professor Per Tuff of Aas, Norway, says the disease, which led to fractures of bones, is much less common than it was fifty years ago, and he attributes this to the better lighting and hygiene of cattle sheds.

My best thanks are due to those who have so kindly answered my inquiries during the past few years as to the conditions in their districts where osteomalacia occurs either among the women or the cattle.

These rough notes are published in the hope that something may be done in Kashmir to investigate still further the conditions of the sunlight there, with a view to the prevention of this disease, to which the lives of hundreds of women and children are sacrificed every year.

NOTES ON THE USE OF LEAD COLLOIDS IN THE TREATMENT OF CANCER.

BY

FRANK COKE, F.R.C.S.,

AND

J. B. COOK, M.D., D.P.H.,

MEDICAL SUPERINTENDENT OF THE WEST MIDDLESEX HOSPITAL.

THE question of the treatment of cancer by lead is now so much before the profession that our experiences with this metal may be of interest.

For some years past we have independently tested new cancer cures as they have appeared in the *English* and foreign journals. The article by Professor Blair Bell in the *Lancet* of 1922 (vol. ii, p. 1005) seemed to be of such importance and to stand on such a rational basis as to invite an early trial of the effect of lead on cases of inoperable cancer. As we did not find it possible to obtain information from Dr. Blair Bell beyond that which had appeared in his articles, a convenient source of lead had to be secured. The aim has been to find a combination of lead with a suitable radicle, the latter, if possible, assisting the absorption or adsorption of the lead. One of the chief difficulties was to obtain a colloidal suspension of the

dispersed lead compound capable of remaining dispersed long enough for general use and of the correct composition for intravenous injection.

The first colloid used was lead oleate. This was freshly made for us at frequent intervals, as it did not keep dispersed very long. It was given intramuscularly. The results gave little encouragement, except that one man with cancer of the fauces seemed to remain stationary; he was neither better nor worse a year afterwards. He died eventually, but the probability seemed that he would have died more quickly without the lead injections. It must, of course, be noted that when first we used these lead compounds we were giving them in very small doses.

The second compound tried was a lead nitro-benzoate, referred to in what follows as "lead N." The use of this was discontinued because we were not able to give any but very small doses without causing some discomfort, chiefly gastric, during the day after the injection.

Next a combination of lead with a very complex radicle of high molecular weight was made. This contained mercury in the same proportion as the lead, but in a non-ionized form. As it was thought that the mercury

might add some antiseptic properties if liberated amongst dead cancer cells, it was retained in the compound. A colloidal suspension of these drugs has been used, and will be referred to as "lead M.A.," the M denoting mercury and the A an amino group. It has been found convenient to refer to these complex bodies by such simple terminology. These colloids have been fully tested on animals as to their immediate toxicity, and found to be harmless. The colloidal suspension of lead M.A. contains 0.1 per cent. of mercury and 0.1 per cent. of lead—that is, one-tenth of a gram, or $\frac{1}{12}$ grains of lead per 100 c.cm., and similar quantities of mercury.

Some twenty cases of cancer have been treated. All of these were naturally inoperable, either from the magnitude of the growth or from its position. Cases were selected in which the cancer was on the surface in some easily observable position. In none of them could the diagnosis be doubted, whilst most had had operations performed on them and the diagnosis confirmed histologically. The results can be divided into four groups.

In the first group of patients are those on whom the lead does not appear to have made the slightest difference, many of them so desperately ill or so full of enormous masses of cancer that no drug could have been expected to influence them, added to which many of them had very small doses.

In the second group temporary improvement was shown. This was manifest by the patients' weight, which had been falling, remaining stationary over a period of many months, or even improving to the extent of a few pounds. The growths often showed considerable decrease in size, firm masses of glands becoming smaller, each gland becoming discrete and freely movable on its fellows. This was due, perhaps, as much to a subsidence of the surrounding inflammation as to any effect upon the growth itself. We may briefly consider five such cases.

1. In an old lady of 76 a hard ulcer firmly adherent to the ribs healed over fairly quickly, and she put on a good deal of weight. She died some months later from hemiplegia; 30 c.cm. of lead N. and lead M.A. were given in twelve doses.

2. A lady with very extensive cancer *en cuirasse*, with many glands in the neck, lost the whole of the hard oedema of the skin. The glands became discrete and freely movable in all directions. For six months she was able to lead a normal life, and took a holiday abroad of seven weeks' duration. During this time she lost ground, which subsequent injections failed to regain; possibly the interval was too long. The cancer cells may have some power of protecting themselves against the lead if

given time to do so. In all, 195 c.cm. of lead N. and lead M.A. were given in forty-two doses.

3. A man with cancer of the larynx, who was given three months to live, and in fact died fifteen months later, showed marked improvement during the first few months and maintained his weight for six months; 216 c.cm. of lead N. and lead M.A. were given in forty-one doses.

4. A very emaciated man who had had his upper maxilla removed at St. Mary's Hospital for a squamous-celled carcinoma showed every sign of healing. Red spots on his face began to disappear and pucker. The stench from his mouth lessened markedly after large pieces had sloughed away. He showed some slight gain in weight, but died suddenly without any very apparent cause. He received 16 c.cm. of lead N. in ten doses.

5. An old lady with a growth in the breast showed a diminution in size of the growth at the end of a year. At one place where it looked very red, like an abscess pointing, the skin became darkened, then almost stained black, and soft as though subsiding. She died from bronchitis. She had had 18 c.cm. of lead N. in seven doses, and 178 c.cm. of lead M.A. in thirty doses.

In the third group are two rather peculiar cases, in which the cancer seemed to abort, the whole of the growth apparently falling out.

The first of these was a woman with a growth springing from the lower jaw involving the cheek and neck. After a few days' apparent improvement the whole cancerous area sloughed out, leaving the bare ends of the lower jaw-bone and a huge fistula opening into the mouth. She received 33 c.cm. of lead N. in ten doses.

The second was a man with a hard, brawny growth filling in the area under the lower jaw-bone. He was getting about the ward, and was not in any way in extremis. There was no breaking of the skin. After a few doses of the lead colloid the whole of this area sloughed away, leaving a huge gaping "cut-throat" wound. The edges were thickened, inflamed, and oedematous, and his face swelled above it, possibly from interference with the lymphatics. He had had 29 c.cm. of lead M.A. in five doses.

Both of these patients died from sepsis soon after the abortion of the growths brought about by the lead.

In the fourth group is the case of a patient whose history and treatment will be considered in some detail. This was a man, 56 years of age in 1925, a worker in a railway electrical department.

Previously to 1920 for many years he had had a wart or mole on the side of his head. This became very sore and somewhat enlarged; it bled slightly at first, then very profusely. He ceased work in 1921. The growth increased continuously. He had no treatment except medicine until 1924, when he came into hospital.

When first seen he was a thin, emaciated, poisoned-looking man, very anaemic, with the skin and sclerotics of a lemon-yellow tint. On the left side of his head, above the ear, he had a huge cauliflower growth, protruding about two inches above the level of the scalp, covered with pus, and very foul-smelling. No glands or metastases were to be found. To-day he is a strong, well nourished man, wishing to leave the hospital and return to work. The growth on his head is not healed and much is still present, but it has become progressively smaller and smaller. It disappeared by minute portions at the periphery, turning to black points and sloughing off.

During the early part of his treatment the growth, after becoming less septic and cleaning up, poured with exudation; later it became quite dry. About this time he also had considerable oedema of the legs and some albuminuria, both of which were considered to be symptoms due to the lead.

The chart reproduced herewith has marked on it this man's progress over many months. The top black line shows those times at which he was receiving doses of x rays. This treatment was given to him by Dr. D. Arthur, radiologist to the West Middlesex Hospital, who has kindly supplied the following details.

"A Sabouraud and Noiré's pastille dose with a water-cooled x-ray tube of 44 inch equivalent spark-gap has been given once or more usually twice a week during those times marked on the chart by the top black line. The rays were filtered through 2 mm. aluminium filter and the growth treated from different aspects (multiple port of entry), no area being treated twice in succession."

Dosage and body weight.

We consider it difficult to apportion the exact amount of credit due to this treatment and to the lead injections, though each may well have assisted the effects caused by the other.

Below this runs a graph of his weight, conforming to the scale on the right-hand side. Taking 12 st. as his normal weight when well, it will be seen that he had lost over 3 st. before treatment commenced; that he rose in weight steadily until he had regained his normal weight, and that he has remained at this for the last nine months.

The vertical lines rising from the base of the chart denote the weekly doses in numbers of cubic centimetres of the lead colloid in use at that time. Weekly intervals on these lines are dated by the months and years at the top of the chart. The numbers underneath the chart are used for reference to this article.

The injections given between (1) and (2) were of lead N. From (3) onwards he was having weekly doses of 10 c.cm. of lead M.A. pretty regularly, and he was putting on weight at a great pace. Part of this increase was due to the very considerable oedema of the feet and legs, as already mentioned, and at (5) he appeared to be suffering from early symptoms of lead poisoning. The injections were therefore discontinued for a short time. At (6) the lead M.A. was recommenced. From there till (7) doses were given intramuscularly; from (7) onwards the intravenous route was used. Owing to the fact that he appeared to be doing quite well as he was, doses were given less frequently from (8) to (9). He was having doses of α rays regularly at this time, but the growth showed signs of increasing in size rather than diminishing, and he was not feeling quite so well. At (9), therefore, full treatment was commenced again, and he at once became better in every respect.

On November 14th, 1924, he gave a *plus* two Wassermann reaction. On November 7th, 1924, Dr. Fletcher examined a portion of the growth, and reported as follows:

"This is undoubtedly squamous-celled carcinoma. The cancer cells are arranged in solid masses, freely infiltrating the sub-epithelial tissue. There are no cell nests."

This man has had up to the present 368 c.cm. of colloidal lead containing 0.36 gram, or $5\frac{1}{2}$ grains, of lead.

The condition of his blood has been extremely interesting. At the commencement of treatment the blood counts, taken several times, showed an average red count of 2,500,000 and a white count of 12,000. The blood on withdrawal looked like thin washy damson juice of a peculiar purplish colour. No normal red cells were to be seen, extreme poikilocytosis being present. His red cell count has increased to 3,600,000 and the white count is 10,000 odd. The differential white count is normal. The freshly shed blood is bright red, and the red cells are remarkably even and regular, though somewhat oval. It is noteworthy that, in spite of the large amount of lead which he has received, his red cells have increased in number and become normal in shape. No stippled cells have been found in his blood.

Full blood counts must be made in all cases, and stippled cells must be frequently sought for. They are quite common, together with polychromasia, in the blood of many cases, often after quite small doses of lead. We are accustomed to record them as the number of stippled cells counted over the number of fields examined, using a 1/12 oil-immersion and a No. 3 eyepiece. Urinalysis is essential when giving full doses.

Occasionally some protein shock has occurred a few hours after an injection—slight shivering, sweating, some rise of temperature, and more rarely some vomiting.

During the cold weather the preparation of lead M.A. is liable to form a gel, but in any case it should always be thoroughly warmed before being injected intravenously.

The injections have all been made with Record syringes of convenient capacity and No. 17 needles. The syringes can be boiled and used immediately while still hot.

No special technique is necessary, but in comparison with similar injections in the case of asthmatics and other patients the giving of an intravenous injection to a cancer patient is often a matter of extreme difficulty. The veins become much shrunken as the patient wastes, and there is a shortage of blood to distend them; they sometimes become hardened pipes of greater substance than an ordinary artery. The lack of supporting fat allows the vein to roll away from the needle as it attempts to pierce the vessel through the leathery skin.

In the series of cases here dealt with the dosage has on the whole been small, and we consider that there is a large margin of safety within which injections of lead can be increased in size and frequency before toxic symptoms from the lead need be expected. But the dosing of any particular case will depend upon a great many different

factors. Patients of large weight with no cachexia will call for large doses. Males will take larger doses than females. Emaciated patients and those with growths which have ulcerated to the surface will require small doses, at any rate to commence with. As any growth may abort, special care must be taken to make such abortion as aseptic as possible. In this connexion the blood supply to the part is probably an important factor. In growths of the gut abortion must be particularly guarded against.

Summary.

We are using a very stable colloidal suspension of lead and mercury (lead M.A.). This can be injected intravenously with the minimum danger of immediate shock or toxicity from the lead. It has undoubtedly had a beneficial effect upon the patient whose case is reported in full in this paper.

We now have a series of cases under treatment with much heavier doses, and the results obtained will be published at a later date.

Arrangements are now being made whereby a supply of lead M.A. will shortly be available for general use.

THE SURGICAL TREATMENT OF TIC-DOULOUREUX.*

BY

G. PERCIVAL MILLS, F.R.C.S.,

SENIOR ASSISTANT SURGEON, GENERAL HOSPITAL, BIRMINGHAM.

Of the various procedures which have been devised for the cure of this most distressing malady two only have stood the test of experience. They are: (1) Some form of alcohol injection. (2) Operation on the Gasserian ganglion by the Hartley-Krause method of approach.

Injection treatment has obvious advantages: it is a minor operation which involves no long convalescence, there is no risk to life, and serious complications are very rare. On the other hand, it is always more or less uncertain in its effects, and the relief from pain is often only temporary.

Open operation on the ganglion has one advantage only, but an important one—with the rarest exceptions it cures the patient, and cures him permanently. My own practice has been to try injection first, and, if this proves unsatisfactory, to operate. During the last five years I have performed fifty-two injections and thirteen operations. In most of the operation cases I had tried injection previously, but in a few cases the patients had been injected elsewhere and refused to have any more. Consequently it would appear that, out of every four cases, three have been reasonably comfortable with injection and one has needed open operation.

TECHNIQUE OF INJECTION.

There are two distinct routes of approach in attempting to inject the Gasserian ganglion—from the front and from the side. From the front it is rather difficult to find the foramen ovale, but, when found, the needle enters easily. It tends, however, at this angle to enter the subarachnoid space rather than the ganglion, and at least one serious disaster has followed injection by this route. The alcohol was evidently injected into this space, and paralysis of a number of important cranial nerves followed.

From the side it is easier to find the foramen ovale, but, on account of the obliquity of approach, the needle tends to stick in the orifice. In some skulls, even with the soft parts removed, it is impossible to pass a needle through the foramen. I believe, however, that alcohol injected into the mouth of the foramen infiltrates through into the ganglion, for after such injections anaesthesia has occurred in the first and second divisions as well as in the third.

I have confined myself to lateral injections, largely on account of the serious disaster already referred to as following an anterior injection. A local anaesthetic is employed so that the sensations of the patient may be

* Abbreviated from a paper read before the Midland Medical Society on November 25th, 1925.

used as a guide. This merely anaesthetizes the skin at the site of puncture, and the patient feels no pain till the point of the needle strikes the third division as it emerges from the foramen ovale. If at the same moment the needle is felt to enter a narrow cavity it is probably in correct position. The syringe is then attached and a few drops of alcohol injected to test the degree of resistance. If the piston slides down without effort the needle has passed to one or other side of the nerve, and the alcohol is not entering the ganglion. The needle is withdrawn a few millimetres and reinserted until a position is found in which there is a definite resistance felt on pushing down the piston. After a few drops have been injected sensation is tested by pricking the skin of the face with a fine needle. The development of numbness confirms the position, and the injection is then completed. I am satisfied if I get anaesthesia of the second and third divisions with numbness of the first, and many cases have been relieved of their pain in which I obtained numbness of the second and third divisions only. Of fifty-two injections I failed in eleven to get satisfactory lasting anaesthesia. This is roughly one case in five. In some of these I reinjected successfully and in the others I operated. I was guided in my choice by the difficulty experienced in injecting, and to some extent by the wishes of the patient.

Results.

Taking cases which were injected at least a year ago, twenty-five have been traced and eleven of these are still free from recurrence. The periods since the injection of these eleven are 12 months, 15 months, 17 months (2), 18 months, 2 years, 2 years and 3 months, 3 years (2), 3 years and 8 months, and 5 years respectively. Cases in which recurrence is known to have taken place are fourteen in number, and the average period of relief was one year and nine months. This hardly gives a fair estimate of the benefit conferred on the patient, for it has frequently happened that the recurrence of pain has been slight and temporary, so that further treatment has not been necessary. For example, a patient reported that she had been quite free from pain except for an attack a year ago, which lasted only a fortnight; this patient regards herself as cured, and is very grateful, but she appears in my statistics as having only one year's relief. It may fairly be said, therefore, of injections that four out of five are successful in giving relief for an average period of twenty-one months, and that there is quite a reasonable chance of the relief being permanent. How great this chance is can hardly be estimated from so small a number of cases, but a rough idea may be obtained by considering the figures quoted above. Of twenty-five cases traced, eleven have remained free, the average time since injection being twenty-eight months. As the cases which recur do so on an average in twenty-one months, it is not unreasonable to hope that most of these will be permanently cured. The only complications experienced in these cases treated by injection were that two patients complained of partial deafness, one in the same and one in the opposite ear. There were no cases of conjunctivitis.

OPERATION.

Operation was reserved for patients whom I failed to relieve by injection, or who had had repeated injections elsewhere and desired more radical treatment. The Hartley-Krause method of approach was used, and in the first few cases I contented myself with dividing the second and third divisions of the nerve inside the skull and injecting alcohol under direct vision into the ganglion. The recurrence of pain in a case treated on these lines by another surgeon led me to doubt the reliability of this procedure, and in subsequent cases two-thirds of the ganglion was removed. The method of dealing with the middle meningeal artery advocated by Jordan Lloyd was adopted, the artery being plugged in the foramen spinosum with a suitable peg (Lloyd used a match), and consequently only needing to be tied in one place instead of two. This makes its division much easier, so long as the peg does not come out.

Results.

I have performed this operation on thirteen occasions, and though some of the patients were over 70 years of age there has been no mortality. Not only was there no mortality, but in only one case was there any cause for anxiety. This was a case in which the peg came out of the foramen spinosum. I had found Jordan Lloyd's matches too soft and had tried an oak peg. This must have been too hard to fit snugly, for violent haemorrhage occurred on the following day, and in my absence from Birmingham my colleague Mr. Rose very kindly tied the external carotid, with an entirely satisfactory result. With this exception, all the cases had a good convalescence. There was a remarkable freedom from ophthalmic complications, and only one case of conjunctivitis has to be recorded. This, however, was severe, and, owing to the patient's refusal of treatment, resulted eventually in loss of vision in that eye. Other complications experienced were a seventh nerve paralysis, due, I think, to forcible retraction of the flap, and a temporary third nerve paralysis which I cannot explain.

All these cases were relieved of their pain with a single exception, but, as my first operation was only done two years ago, I can produce no evidence of permanent cure from my own experience. It is, however, well recognized that in all but the rarest cases removal of the ganglion cures the condition permanently. In fact, I have felt justified in telling my patients that, though the operation is severe, the cure is certain. This confidence was rudely shaken a few months ago by the last case I operated upon. The operation proved exceptionally easy, and I had such a perfect exposure of the ganglion and its roots that I was led to try the operation of division of the sensory root instead of resection of the ganglion. The patient had absolutely no relief whatever. As this was my first failure I naturally attributed it to the different operation I had performed, and said hard words to myself for trying to paint the lily. I explained the position, and suggested that I should make sure of relief by removing the ganglion. I then removed the lower two-thirds of the ganglion with a part of the mandibular and maxillary nerves, and had the removed tissue microscopically demonstrated the ganglion cells. There was not the slightest relief from pain! This was either a case in which the lesion was on the central side of the ganglion or one of purely subjective pain. The patient showed obvious signs of mental derangement, but these had naturally been attributed to the severity of her suffering.

Of the remaining eleven cases the pain has recurred in one. This was one of the earliest operations in which the ganglion was injected and not removed, and occurred in the patient who developed conjunctivitis. It has finally destroyed any hope I had that injection of alcohol under direct vision might prove a satisfactory alternative to excision.

It has been suggested that though the operation relieves the pain it turns the patient into a chronic invalid. Of two patients who recently wrote to me, one is working as a collier in a mine, and the other is the successful head mistress of a large school for girls.

ACTINOMYCOSIS SUCCESSFULLY TREATED BY IODINE IN MILK.

BY

HUBERT CHITTY, M.S.LOND., F.R.C.S.ENG.,
SURGEON, BRISTOL ROYAL INFIRMARY.

THE rapid and uninterrupted recovery of four consecutive cases afflicted by this distressing and usually fatal malady seems worthy of record.

The treatment adopted was evolved as the result of an observation made during the course of the following fatal case.

Late Treatment: Death.

A. S., a farm labourer, was admitted to the Bristol Royal Infirmary under my care in February, 1925, suffering from what appeared to be acute appendicitis. The appendix was removed. It was situated behind the caecum, and was bound down by dense adhesions. After an uneventful recovery the patient was

discharged to a convalescent home in March. Four weeks later a small abscess in the scar was opened in the casualty department.

He was readmitted in July with an abscess below Poupart's ligament, flexed hip, pain on walking, and a mass in the right iliac fossa. The diagnosis of actinomycosis was made, and confirmed by the recovery of the organism from the pus.

He was treated by x rays, large doses of potassium iodide, by vaccines (both stock and autogenous), and later by colloidal iodine given by the mouth and injected into the sinuses. His progress was, however, steadily downward.

In December he was bedridden and apparently moribund. The whole peritoneum seemed to consist of one huge abscess, which extended down the thighs almost to the knees. No doubt a very mixed infection was present.

About this time our pharmacist, Mr. A. L. Taylor, expressed the opinion that colloidal iodine contained little if any iodine in a colloidal state, and suggested that tincture of iodine freshly added to milk would give a more truly colloidal solution. The patient was therefore given this preparation by the mouth.

Within a week the sinuses had all closed, and he was out of bed greatly improved in his general condition. Unfortunately, in April a fresh abscess, containing staphylococci and other organisms, re-formed in the abdomen, and he died on April 29th, 1924.

The Four Successful Cases.

During the period of improvement in the case just recorded my colleague Mr. C. F. Walters showed me a similar case.

CASE I.

A boy, who also had been operated upon for appendicitis, subsequently presented intensely hard chronic inflammatory masses in the abdomen; they spread across to the left iliac fossa, and finally invaded the skin. In places small areas of softening were noted. At my suggestion this patient was given the same preparation of iodine and milk.

The effect was almost incredible, for in a few weeks the masses had melted away and not a trace of the disease remained. The boy has remained perfectly well ever since.

It will be observed that no opportunity arose of confirming the diagnosis microscopically, but clinically it was as definite a case of actinomycosis as one could possibly meet.

Mr. Rendle Short adopted the same line of treatment in the following case.

CASE II.

The patient was a girl who had suffered from actinomycosis of the jaw and face for five years. The organism had been recovered from the pus. She had undergone numerous operations, including removal of portions of the lower jaw and zygoma. In spite of very free removal the disease always recurred. In November, 1924, she too was put upon iodine and milk. Seeing that bone was invaded a rapid response could hardly have been expected in this case, and one further abscess did develop in January, 1925, but since then all sinuses have healed and she appears to be completely cured.

CASE III.

In December, 1924, a butcher was sent to me by Dr. Dix of Clifton. This man had a large left-sided abdominal tumour. It was palpable by the rectum, and extended to the lower border of the ribs. It was proved by incision and microscopic examination to be actinomycotic in nature.

The same treatment was carried out, and within three weeks no trace of the tumour could be detected. The patient has remained perfectly well ever since. Skin markings showed that the diameter of this mass, which felt like a lump of wood, sometimes diminished by fully an inch within twenty-four hours.

CASE IV.

The last case, a young woman, was also under the care of Mr. C. F. Walters. She had a hard inflammatory mass in the neck, attached to the lower jaw. Several small abscesses in connexion with this had been opened during the course of some six weeks. In March, 1925, another abscess was opened and typical sulphur granules were discovered in the pus.

After a fortnight's treatment on the same lines as the other cases all sinuses were soundly healed and no trace of the inflammatory mass remained.

There appears to be no necessity to push the dose of tincture of iodine; 5 to 10 minims in half a cup of milk taken three times a day have proved ample, though more can be given without any harmful results.

In looking through the literature bearing upon the subject of actinomycosis I have only been able to find one case in which treatment produced results at all comparable to those obtained in these cases. This was recorded by Bigland and Sergeant in the *BRITISH MEDICAL JOURNAL* of July 14th, 1923 (p. 61). The patient in this case was a man suffering from actinomycosis of the lung complicated by empyema; he recovered after having his empyema cavity washed out with colloidal iodine, which drug was also administered intravenously. In addition he was given large doses of potassium iodide by the mouth. Possibly colloidal iodine given intravenously,

although it contains little iodine in a colloidal form, may produce the same curative effect as does a truly colloidal solution when given orally.

I hope that this article may attract the notice of the veterinary profession, and that a trial may be given of this method of treatment in the case of animals.

In conclusion I must express my indebtedness to my colleagues Mr. C. F. Walters and Mr. Rendle Short for permission to make use of their cases in conjunction with my own; to Mr. A. L. Taylor for his happy suggestion as to the best way to make colloidal iodine; and to Professor McBain for his kindness in demonstrating the fact that when tincture of iodine is added to milk it does make a truly colloidal solution.

RUPTURE OF ANEURYSM ON BRANCH OF LEFT RENAL ARTERY, COMPLICATING PREGNANCY.

BY

A. E. CHISHOLM, F.R.C.S.ED.,

ASSISTANT TO DEPARTMENT OF GYNAECOLOGY AND OBSTETRICS,
ROYAL INFIRMARY, DUNDEE.

On November 5th, 1924, a woman, aged 28, about seven months pregnant, was brought to the maternity department of the Dundee Royal Infirmary in a very collapsed condition. The pulse was rapid and weak, and the face was very blanched.

According to the history, treatment had been carried out for the past three months for cystitis with frequency of micturition. The patient had had a miscarriage about a year before. The present acute condition dated from the day prior to admission (November 4th). The statement made was to the effect that while walking she was suddenly seized with severe pain in the back and almost collapsed. She was seen by a doctor, but the medicine he gave was at once vomited.

The patient was admitted to hospital at about 11 a.m. Accidental haemorrhage was suspected, but there was no sign of blood externally. Examination of the abdomen did not tend to confirm the original provisional diagnosis, however. A very hard and acutely tender resistant area was felt in the left flank. It was considered wise to keep the patient under observation before intervening, and thus give her time to settle down in hospital, with the possibility of some improvement taking place. I saw her again at 4 p.m., when her condition was even worse than before, as vomiting had supervened, rather suggesting the possibility of intestinal obstruction. It was decided that an exploratory laparotomy must be done, in spite of the very critical condition of the patient. She was certain to die if left alone, and it seemed that operation would give her the only chance of recovery, although a very poor one.

Somewhat later, therefore, I opened the abdomen under ether anaesthesia, some 1/2 per cent. novocain being injected into the muscles. The incision was to the left of the mid-line, the rectus muscle being pulled outwards. A normal pregnant uterus was found, and the intestines were not unduly distended. On palpation the right kidney seemed to be very small. The explanation of this will be seen in the pathological report. A large hard retro-peritoneal mass was present on the left side, and discoloured blood was seen between the layers of the mesentery of the pelvic colon and, to some extent, round the gut, in the region of the descending colon and pelvic colon. The mass turned out to be a very large blood clot.

I opened the posterior parietal peritoneum over the swelling, but very little blood came away, as clotting had already taken place to some extent. It would have been running an unjustifiable risk to begin clearing away the clot. A moment's uncontrollable bleeding would certainly have caused immediate death. A drain was inserted through a stab wound in the left flank to the region of the clot—although there was little chance of much drainage taking place—and the opening made in the posterior peritoneum was closed as far as possible. The abdomen was closed in layers. Shortly afterwards the patient died. This was expected, considering her condition.

Fortunately a *post-mortem* examination was allowed. The parts involved, including the gravid uterus, were removed *en bloc* and hardened before dissection. The following are some of the points in the immediate pathological report by Dr. F. M. Milne. Only the main points will be mentioned.

"There is some atheroma in segment between aortic and mitral valves."

"There is a large retroperitoneal haemorrhage extending from left pelvic brim upwards to behind the spleen. It lies particularly around the kidney in the form of a large coagulum, which compresses the kidney tissue. The kidney, with the mass of blood, weighs 4 lb. (approximately). The haemorrhage extends into the left broad ligament, and also within the mesentery of the descending colon; it was found even close to lower border of pancreas. The right kidney shows hydronephrosis. Spleen normal in size, pale in colour. Liver pale and fatty; no gall stones. Stomach and intestines normal. Suprarenals normal."

When palpated during the operation the hydronephrotic right kidney must have been fairly empty, and only the lower pole of kidney substance was left, thus suggesting a small kidney.

Later I did a careful dissection of the specimen. This was rather difficult, as the clot was so hard, and I had to be very careful to avoid cutting anatomical structures which might be involved in it. Eventually, however, a small aneurysm was found on a branch of the left renal artery. The sac of the aneurysm was about the size of a pea and had ruptured. There was no history of trauma to account for the rupture. The presence of an aneurysm at this site must be very rare, and it would be especially unexpected in a woman of the age of the patient under consideration.

Dr. Tudhope of the pathological department of University College, Dundee, examined a section of the aorta, but he

did not find anything microscopically to suggest a syphilitic endarteritis.

Dr. Christine Thomson examined the child. Even if syphilitic, it would have been impossible to find spirochaetes after the preserving of the specimen, and there had been no opportunity for having the Wassermann test done on the mother's blood.

The following are some points noted by Dr. Thomson.

"The baby is very suspicious of syphilis; *S. pallida* not found; autolysis of viscera.

"Splenic enlargement present, also definite adhesive peritonitis. Periportal fibrosis in liver, commencing to spread, but no definite mononuclear cirrhosis. Very slight fibrosis of spleen. Spleen much enlarged. Chondro-epiphysitis of femur (indefinite). Placenta suspicious of syphilis."

Thus the presence of syphilitic infection of the child is only suspected, but the signs are inconclusive.

Rowlands¹ reported the case of a married woman, aged 47, who suffered from severe haematuria for three weeks. Blood was seen coming from the left ureter. The left kidney was removed. On examining the kidney a ruptured sacculated aneurysm, the size of a large pea, was found, partly on the surface of one of the lower renal papillae and arising from an intrarenal branch of the renal artery. There was no history of recent injury or illness. The aneurysm was seen after opening the pelvis of the kidney. The patient recovered. The site of this aneurysm would, in all probability, appear to be less dangerous than that of the one under review.

It would be inferred that aneurysm of the splenic artery, although rare, is of more frequent occurrence than that of the renal artery or one of its branches.

Fitzwilliams² reports a case in which there were three aneurysms of the splenic artery, one of them having ruptured. Operation was performed, but the patient was beyond help. She was a woman of 27, with no other sign of disease. Symptoms suggested rupture of a gastric ulcer or of an ectopic pregnancy.

Baumgartner and Thomas³ give an analysis of forty examples of aneurysm of the splenic artery collected from

literature. It would appear that certain diagnosis of the condition before rupture is practically impossible, although the condition may be suspected in rare cases. Such an aneurysm may be of considerable size, and yet it may be impossible to palpate it.

Garland⁴ reports an interesting case of rupture of a splenic artery aneurysm simultaneously with paracentesis of the abdominal cavity, when 1 litre of fluid was drawn off. The trocar did not wound the aneurysm. In all probability even such moderate relief of intra-abdominal tension may have been sufficient to determine rupture of the aneurysm.

It is stated that out of some 4,100 autopsies in Massachusetts General Hospital only three cases of aneurysm of the splenic artery were found.

I am indebted to Dr. R. C. Buist for permission to publish this case.

EXPERIMENTAL PASSAGE OF THE OOCYSTS OF FISH COCCIDIA THROUGH THE HUMAN INTESTINE.

BY

J. G. THOMSON, M.A., M.B., CH.B.,
DIRECTOR, DEPARTMENT OF PROTOZOOLOGY,

AND

ANDREW ROBERTSON, M.B., CH.B.,
ASSISTANT IN PROTOZOOLOGY,

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.

In the BRITISH MEDICAL JOURNAL of February 13th (p. 262) the authors pointed out that three coccidia described in man—*Eimeria wenyoni* Dobell, 1919, *Eimeria oxyphora* Dobell, 1919, and *Eimeria snijdersi* Dobell, 1921—were not true human parasites, but corresponded morphologically to the oöcysts of two species common in the liver and testis respectively of certain fish. *Eimeria sardinae* Thélohan, 1890 (of which *E. oxyphora* and *E. snijdersi* become synonyms), is present in the "soft roes" (testes) of about 100 per cent. of herrings, occurs in enormous numbers in the soft roes of sprats, and is somewhat less frequent in the testes of mackerel. It is interesting to note that, since the previous communication was published, this parasite has been found in tinned sardines (*Clupea pilchardus*) exported to this country from Portugal, and also in tinned soft roes of herrings from Norway. In spite of the high temperatures to which these articles of diet must have been subjected during the cooking processes at the factories, the oöcysts were in a remarkable state of preservation, and their contents were easily differentiated. *Eimeria clupearum* Thélohan, 1894 (synonym *E. wenyoni*), is confined to the livers of the same group of fish, and its oöcysts are especially numerous in the livers of herrings. These coccidia provide a striking example of two distinct, but closely allied, species selecting different organs of the same fish for their development. Wenyon (1915), in his original description of the oöcysts of this coccidian in the faeces of man, compared them with those of *Eimeria faeciformis*, which is parasitic in the intestine of the mouse, and he obviously suspected that man derived the infection from some animal source. Brug (1922) mentioned in the literature that these *Eimeria* might simply be ingested with the food, basing his suggestion on the fact that natives frequently eat insects and also the intestines of animals. Brug also suspected that the distorted forms of an *Eimeria* seen by Snijders (*E. snijdersi* Dobell, 1921) in a case in Sumatra might be the result of cooking.

It will be noted that up to the present no one suspected fish as the source of these *Eimeria*, and, further, that until the authors undertook this investigation and actually found the oöcysts in herrings, there was no mention or suggestion in the published literature of the possibility of fish being incriminated. The salient fact is that the discoveries of Thélohan made over thirty years ago have remained more or less buried in the literature, and it is almost inexplicable

Left kidney from behind. A, aneurysm; B, left renal artery; C, aorta; D, inferior vena cava; E, left renal vein; F, left kidney—small on account of pressure.

that these parasites should only now be traced to the herring.

To prove that the oöcysts could pass through the human intestine the following experiment was undertaken. A volunteer was given a strong saline soon after the midday meal, which resulted in a copious evacuation about 6 p.m. A pound by weight of herring soft roes heavily infected with *E. sardinae* was cooked by frying in butter and seasoned with salt, pepper, and lemon, and about three-quarters of these were eaten at 8 p.m. No other food was taken until the following morning, when, at 10 o'clock, a semi-fluid motion was obtained, and this, on examination, was found to contain the oöcysts. In the stool they were relatively numerous, two or three on the average to each cover-slip preparation, and these corresponded in every way with oöcysts previously seen by the authors in human stools. The next stool passed by the volunteer showed no oöcysts, and he suffered no ill effects.

This experiment places beyond doubt the origin of these *Eimeria* in human faeces, and, although an experimental meal of herring's liver (with *E. clupearum*) has not been given yet, there is no reason to suppose that the result would be any different from the above. These oöcysts of *E. sardinae* and *E. clupearum* must be eaten every day by large numbers of individuals.

MEDICAL, SURGICAL, OBSTETRICAL.

THREATENED GANGRENE OF THE ARM DUE TO INJURY OF THE MAIN ARTERY.

I HAVE read with interest Mr. Peter McEwan's communication on this subject in the *JOURNAL* of January 30th (p. 186), and should like to offer a few suggestions on the treatment of similar cases, as the result of experience gained during the war.

In the first place, rupture of the main artery in a patient under 45, even if unassociated with damage to the accompanying vein or venae comites, is unlikely, of itself, to cause gangrene in the upper extremity, where the collateral circulation is notoriously free. When gangrene occurs in such circumstances it is probably due to the tension of a haematoma, which seriously impedes the arterial flow and the venous return, by compressing not only the main vessels but also those concerned in the collateral circulation.

The correct treatment is to remove the haematoma and deal with the artery and vein, or veins, at the injured spot. Take, for instance, the case of a wound or rupture of the axillary artery, with the formation of a diffuse traumatic aneurysm in the axilla. The third part of the subclavian artery on the affected side is controlled by firm pressure against the first rib—or better, I think, by a temporary ligature, or an arterial clamp, which compresses the artery but does not damage its inner coat. The axilla is now opened up, all clots are cleared out, and the injured vessel is sought for. A small opening in the artery may be made evident by a momentary release of the pressure controlling the subclavian. A spurt of haemorrhage immediately reveals the injured spot. If the artery is completely torn across ligatures are applied to both ends. If incompletely severed it is wise to complete the division and tie both ends. In the case of a small wound I have been able to suture the opening without occluding the artery. (This was in a patient in whom the accident happened during the removal of a breast for carcinoma.) The ideal method in all cases would, of course, be arterial suture, but, except in those cases in which the collateral circulation has been seriously interfered with, the method described is sufficient. If the axillary vein is injured it can be dealt with in the same way as the artery. Experience during the war showed that ligature of the accompanying vein or venae comites

in arterial injury, so far from increasing the risk of gangrene, actually lessened it by retaining in the limb a quantity of blood useful for its nourishment. All bleeding points having been secured, the temporary ligature or clamp is relaxed, and, if no further haemorrhage takes place, is finally removed. The wound in the axilla may be sutured without drainage, or a strip of rubber left in for twenty-four hours.

In injury to the brachial artery the procedure is even simpler, as a bloodless field can be secured by a tourniquet applied above the suspected rupture. The clots are turned out, and the artery and vein, or veins, dealt with as described.

Mr. McEwan's cases were both late cases, and my object is, not to criticize adversely his treatment, but to emphasize the importance of relieving pressure at the affected spot at the earliest opportunity. If this is done gangrene can be prevented, unless some other complication is present.

ANDREW FULLERTON,
Professor of Surgery, Queen's University,
Belfast.

SEPTICAEMIA DUE TO *B. AERTRYCKE*.

THE following case presents several features of interest, and seems, therefore, worthy to be put on record.

A man, aged 46, was admitted to the Devon Mental Hospital on October 1st, 1925, in a state of acute mania; in this state he remained until October 21st, when symptoms of bronchopneumonia set in, and terminated fatally the same day.

At the *post-mortem* examination the appearance of the different organs of the body suggested the possibility of septicaemia: the lungs were very congested, and there was evidence of commencing abscess formation at the left base; the intima of the aorta had a faint pink appearance; the liver and kidneys were congested and showed evidence of cloudy swelling, while the spleen was large, soft, and pulsatious, and the intestines generally injected. Cultures were accordingly made, with the usual precautions, from the interior of the left ventricle of the heart. An organism was isolated, which on further investigation gave the biochemical and serological reactions of *B. aertrycke* (Mutton).

It was proved that, during his sojourn in hospital, the patient had been on a fluid or semi-fluid diet, but as several of the patients in the same ward had about this time partaken of brawn, this was subjected to bacteriological examination, with negative results. A point of considerable interest is that the patient came from Lynton. During the summer of 1925 there was a small outbreak of food poisoning in this area, and a strain of *B. aertrycke* was proved to be the causal agent. Inquiry of the patient's relatives elicited no history of previous intestinal trouble; he was apparently a casual labourer, and had been in farm service for several years when a lad.

Our findings were confirmed by Dr. W. G. Savage, county medical officer of health for Somerset, and by Mr. Bruce White of the Lister Institute, to both of whom our thanks are due.

The salient features of this case are: First, the unusual source of the organism—namely, the heart blood. The patient was much too ill during life to attempt blood culture, and as the possibility of an intestinal pathogen was not contemplated at the *post-mortem* examination, the intestines were not examined bacteriologically. We cannot be certain, therefore, whether the presence of the organism in the general circulation was a terminal phenomenon or not. Secondly, the specificity of the strain obtained—a point noted both by Dr. Savage and by ourselves. The organisms included under the comprehensive heading of the "Salmonella Group" are very closely interrelated, both biochemically and serologically, and can usually only be differentiated by agglutinin-absorption procedures: in this case, however, the organism in question agglutinated with a *B. aertrycke* serum up to a dilution of 1 in 250, and was absolutely unaffected by the serums of allied strains. The serums employed were those of the Standards Laboratories at Oxford. Thirdly, the fact that the patient came from an area in which there had already occurred an outbreak of food poisoning due to the same strain of organism.

These notes are published by kind permission of the medical superintendent, Dr. R. Eager, O.B.E., to whom our thanks are due.

Reports of Societies.

INTRATHORACIC NEW GROWTHS.

At a joint meeting of the Sections of Medicine, Electro-Therapeutics, Surgery, and Laryngology of the Royal Society of Medicine, held on February 23rd, with the President of the Section of Medicine, Dr. HUGH THURSFIELD, in the chair, a discussion was held on the diagnosis and treatment of intrathoracic new growths.

Dr. L. S. T. BURRELL, opening the discussion, pointed out that only a few years ago such a subject attracted mere academic interest, but nowadays, when it was being discovered that these new growths in the thorax were not so uncommon as previously supposed, and that they were in some instances amenable to treatment, the question became one of practical importance. He dealt with intrathoracic new growths under three groups: those of the mediastinum, those of the pleura, and those of the lung. In each case the new growth might be primary or secondary, malignant or benign. In general the diagnosis of secondary tumours was easy, and they were beyond cure. Primary tumours, and especially the benign ones, which could prove fatal on account of their size, were, however, curable in certain cases. Dealing with mediastinal new growths, Dr. Burrell described sarcoma as being the commonest, fibromas and dermoid tumours also occurring. In the early stages the signs were those of pressure. He described one case where a patient complained of swelling of the veins over the right side of the neck on stooping. Another striking case presented well marked changes in certain joints, and on examination of the chest a mediastinal tumour was found. This was treated by three applications of x rays, and both the tumour and the joint affection disappeared. The tumour recurred, and was again successfully treated. Death followed four years after the first discovery of the growth, which proved to be lymphadenoma. In many cases of mediastinal new growth a pleural effusion occurred early, but generally not until other signs had made the diagnosis obvious. Pain and dyspnoea also occurred early, but x -ray examination of the chest was the only certain and accurate method of diagnosing mediastinal new growths in their earliest and curable stages, for certain cases were suitable for surgical treatment. Dealing next with tumours of the pleura, of which the majority were endotheliomata, Dr. Burrell described the earliest symptom as dyspnoea due to a large pleural effusion. The diagnosis in these cases was usually obvious, and no treatment was of any value. Confirmatory evidence of the disease could be obtained by thoracoscopy and also by withdrawing the pleural fluid, which was frequently blood-stained, but not always so. Coming to new growths of the lung, Dr. Burrell pointed out that these were not so uncommon, accounting for at least 1 per cent. of all cases of carcinoma. Tuberculosis was held to be a predisposing cause, and frequently occurred with the neoplasm. Hence, since the upper lobe was affected more commonly in both these conditions, diagnosis might be extremely difficult. Nevertheless, early diagnosis was of great importance, since operation offered some chance of a cure, impossible by any other means. The physician should always be on the look-out for something unusual in his tuberculous patients, and he should not fall into the fallacy of disregarding a persistently negative sputum report. About 80 per cent. of all cases of carcinoma of the lung began in a bronchus, and hence bronchoscopy was of value. Once the diagnosis was made a surgeon should always be consulted, since radiation therapy, except in cases of lymphadenoma, was disappointing, and both innocent and malignant tumours of the lung, otherwise certainly fatal, could and had been removed by operation.

Mr. SOMERVILLE HASTINGS said that to laryngologists new growths in the thorax made themselves known by pressure on the vagus, causing laryngeal symptoms, by pressure on the oesophagus, and by pressure on the trachea or main bronchi. Pressure on the vagus generally gave rise to the usual paralytic affections of the larynx. In the early stages there was considerable difficulty in breathing, which was noisy, and in cases of pressure by malignant tumours intubation was the most satisfactory treatment to tide the

patients over this stage until complete paralysis set in. With regard to pressure on the oesophagus, Mr. Hastings stated that more accurate information could be obtained by the oesophagoscope than by an opaque meal and x rays. In treatment of oesophageal obstruction well screened radium was sometimes useful. Pressure on the trachea and bronchi could be brought about by various tumours, both inside and outside these passages. By getting the patient to bend well forwards the interior of the trachea could sometimes be seen with a laryngeal mirror, and the bronchi could be examined with a bronchoscope. In skilled hands, Mr. Hastings emphasized, the risk of bronchoscopy was practically negligible. By means of bronchoscopy a growth could be recognized, a piece removed for section, opaque substances could occasionally be introduced to help subsequent x -ray examination, a growth could be removed, or radium could be applied. Further, if sepsis had occurred the patient's comfort could be increased by lavage through a bronchoscope.

Mr. J. E. H. ROBERTS emphasized the importance of early diagnosis, since operative surgery had now made it possible to remove intrathoracic new growths in their early stages. Suspected cases should be submitted to special methods of examination, such as bronchoscopy and thoracoscopy. Dealing only with the neoplasms of the thorax, Mr. Roberts pointed out that innocent ones were rarer than the malignant varieties, but they were being detected more frequently now by means of x rays. Dermoid cysts in the anterior mediastinum and fibromas growing from the posterior mediastinum were the most important. Symptomless though these tumours might be at first, they eventually caused pressure symptoms and death. Means of access to these tumours was obtained either by a sternum-splitting operation which avoided opening the pleura, and which was suitable for growths at the apex of a lung, or by a transpleural operation. Of the malignant tumours the primary sarcomas of lung and mediastinum did not come properly within the surgeon's reach. Radiation treatment was to be preferred, but eventual cure was not to be expected. Primary carcinoma of the lung appeared to be becoming common; it arose usually from a bronchus and rarely from the parenchyma of the lung. It caused obstruction of the lumen of the bronchus with collapse of part of the lung and, later, bronchiectasis. Since operation in these cases where infection had occurred was very dangerous, the surgeons hoped that it would be possible to diagnose the new growth before degeneration and sepsis set in. Palliative operations to drain abscesses in these cases were, however, worth while. Mr. Roberts concluded by showing some striking skiagrams of cases before and after the operative removal of intrathoracic new growths.

Dr. STANLEY MELVILLE pointed out that in the pre-radiological days the publication of a case of neoplasm in the chest was a rarity, and clinical medicine rather failed with regard to this condition, partly because it was thought too rare and partly because the hopelessness of the outlook did not encourage diagnosis. Nowadays, given satisfactory team work between all concerned, it should soon be possible, Dr. Melville believed, to make a working diagnosis in any case of intrathoracic new growth. Dealing first with the benign neoplasms, he described the x -ray diagnosis of fibroma, and pointed out how collapse of the lung helped in the diagnosis. This diagnostic collapse was a simple and harmless procedure and ought to be of universal use. In the case of a dermoid cyst in the chest x -ray diagnosis was rendered difficult by the dense opacity of the contained sebaceous material. Dealing next with malignant neoplasms, Dr. Melville pointed out the apparent increase in their occurrence, showing some recent statistics indicating that carcinoma of the lung accounted for over 4 per cent. of all cases of carcinoma. He asked whether this increase was real or apparent. Bronchial stenosis appeared to be the first result of carcinoma of the lung and it gave an almost unmistakable picture. In the upper part of the lung cases of primary carcinoma provided a very characteristic x -ray picture only to be confused with lobar pneumonia. In the lower part distinction was more difficult owing to the obscurities produced by pleural involvement. In secondary

neoplasms of the lung both sarcoma and carcinoma were very similar in appearance, but the distinction was not of much importance. In the case of mediastinal tumours collaboration between a clinician and a radiologist was of greatest importance. It was the duty of the radiologist to prove that the mass was not connected with the aorta, and the strict lateral position was of great help. The radiologist could also diagnose retrosternal thyroids, and should employ opaque meals to see if any tumour present pressed upon the oesophagus. Dr. Melville showed numerous skiagrams to emphasize certain points, and concluded with a strong plea for more team work and free discussion on this subject.

Dr. ROBERT KNOX dealt mostly with the treatment of intrathoracic new growths by means of radiation. He emphasized the importance of diagnosis, since aneurysm was often mistaken for a new growth. He described a case of lymphosarcoma which was first treated successfully by buried radium and, on the recurrence of the tumour two years later, by x rays. The latter again produced disappearance of the tumour. X-ray technique was still improving and big doses could be given by this method, avoiding the necessity of operating in order to insert radium. A second case, also successfully treated by means of x rays, was a mediastinal tumour secondary to a new growth of the testicle. A third case, of secondary sarcoma, had failed to respond to any radiation treatment.

Dr. R. HILTON described how the introduction of a small amount of air into the chest greatly helped in the diagnosis of intrathoracic neoplasms associated with pleural effusion by lowering the level of the fluid. Pneumothorax was not only confined to diagnosis, but should be performed as a preliminary to surgical intervention. Air should only be introduced at atmospheric pressure and not forced in. Collapsed lung favoured operative procedures being easier to manipulate.

Sir CHARLTON BRISCOE dealt with the diagnosis of involvement of the phrenic nerve by tumours at some point in its course. Certain areas of deflation of the lung followed paralysis of the phrenic nerve, and these could be detected by certain areas of dullness on examination of the chest. X-ray examination was also important, and since lung deflation was apt to produce obscurities in the region of the diaphragm an exact mapping out of the limits of its movement on the affected and sound sides was very important.

Dr. F. G. CHANDLER pointed out that the early diagnosis of innocent tumours was often by chance on a routine radiological examination of the chest. Enlarged veins on the chest were not usual in these cases, being more commonly due to aneurysm, gumma, or substernal thyroid. He described one case of primary sarcoma successfully treated by x rays, but had never seen any other such case benefited by this form of treatment.

Dr. DEVEREUX FORREST described the results of 152 cases of intrathoracic neoplasm occurring in the last twenty years at the London Hospital. According to Professor Turnbull, these were all cases of carcinoma, the oat-celled sarcomata of the posterior mediastinum being in reality medullary carcinoma of the bronchial epithelium. Dr. Forrest emphasized the symptoms and signs in some detail, and produced charts which seemed to indicate that the occurrence of new growths in the chest was really on the increase. He pointed out that secondary deposits in the liver from new growths of the lung were extremely common.

The PRESIDENT uttered a note of warning against accepting statistical proof that the disease was on the increase, since admissions to the London hospitals had nearly doubled in the last twenty years, and cases were now admitted which previously were always relegated to the infirmaries. Mr. T. P. DUNHILL emphasized the difficulties of diagnosis, showing three very similar skiagrams from cases of endothelioma, aneurysm, and retrosternal thyroid. He described several other cases of retrosternal thyroid tumours. The PRESIDENT pointed out that early dyspnoea as a symptom had not been sufficiently emphasized. He also advised clinicians to study their patients more frequently with the aid of the x-ray screen. Mr. ROBERTS and Dr. MELVILLE briefly replied.

EXPERIMENTAL EPIDEMIOLOGY.

At a meeting of the Section of Epidemiology and State Medicine of the Royal Society of Medicine held on February 26th, Drs. MAJOR GREENWOOD and W. W. C. TOPLEY contributed a paper entitled "Experimental epidemiology: Some general considerations."

The chief difficulties encountered in the study of human epidemic disease, they said, were that the data, although extremely numerous, were not compiled on a uniform plan, and that changes, both of professional opinion and, still more, of the economic and social conditions of a human population, rendered continuous observations of the course of an epidemic disease under uniform environmental conditions impossible. An experimental method had the advantage that environmental changes (other than those it was actually desired to study) could be maintained constant over a period which, having regard to the relative lengths of life of men and mice, was much longer than the whole modern history of infectious disease.

The bulk of the experiments described in the paper related to colonies of mice wherein a fatal infectious disease due to a pasteurilla existed; the colonies were recruited by the immigration of healthy mice which had been subjected to a long quarantine and were not carriers of the infective organism. In different experiments the rate and method of immigration were varied. In one series the additions ranged from six daily down to one every third day. One of these experiments had been continued for five years, which, assuming that on the average a human life was thirty times as long as the life of mouse, corresponded to a period of human observation of 150 years, and the medical statistics of the community were compiled and analysed with the same care as those of a human population. The statistical history of this community was described, and it was shown (1) that the death rate exhibited the same quasi-periodic variations, epochs of great and small mortality, as human medical statistics of infectious diseases display; (2) that although throughout the whole period no animals infected with pasteurilla entered the community, that infection produced at intervals epidemics of pasteurilosis; (3) that an infection with the Gaertner organism which the quarantine failed to exclude led to epidemics which in their relation to the pasteurilla epidemics produced effects comparable with the phenomena which, in human experience, the doctrine of epidemic constitutions had been invoked to explain. The authors suggested that, as in the colonies of mice living under uniform environmental conditions variations of cosmic phenomena could hardly be required to explain the epidemic successions, that hypothesis might perhaps be also unnecessary in connexion with human epidemiology. Another experiment was described in which during 325 days not a single death from pasteurilosis occurred—that is, in human experience some twenty-seven years—and no infected animals were admitted, yet the disease again became epidemic. As the number of daily admissions increased the rate of mortality tended to increase and the intervals between successive epidemics to decrease, but large discontinuous additions—for example, adding 50 or 100 mice at long intervals—did not have the same effect upon the mortality as small continuous additions. It was suggested, therefore, that the determining factor was not so much a critical arithmetical ratio of carriers to susceptibles in a population as the continuous addition of susceptibles. Knowledge of the mechanism of natural infection in human disease was very imperfect. Such data as those of Dr. McClure implied that the proportion of susceptibles exposed to infection who were actually infected did not always vary with the ratio of susceptibles to infecting cases—that is, that the attack rate in families of three was the same as in families of two when the initial infecting case was not removed (scarlet fever).

Finally some experiments were described designed to test whether the relative immunity of animals which had passed successfully through an epidemic of infectious disease, in comparison with animals which had never been exposed, were a consequence of selection (the naturally unresistant weeded out by death) or of active immunity due to sublethal infections. To this end two infected colonies were

established, one of which received immigrants from the other and from a clean stock. It was shown that the advantage of the immigrants from an infected colony over unsalted stock was more easily explained on the hypothesis of immunization than on that of selection, although both factors were probably at work. Length of exposure rather than severity of the disease (measured by the death rate) during the period of exposure seemed to be the important factor of the advantage derived by the survivors.

TESTING OF RENAL FUNCTION AND TREATMENT OF RENAL DISEASE.

At a meeting of the Section of Urology of the Royal Society of Medicine on February 25th, with Mr. JOCELYN SWAN in the chair, papers were read on the testing of renal function and treatment of renal disease.

Professor HUGH MACLEAN said that there were from fifteen to twenty possible tests of renal function, and each year saw additions to them, with some falling into desuetude. To have a great number of tests was of no value. With experience of a few tests, the renal condition of practically every patient could be ascertained. The minimum number of tests he used was two—namely, the blood urea and the urea concentration tests. While he agreed that 20 mg. per 100 c.cm. was the average quantity of urea in the young person, as people got older the urea concentration rose, so that at about 60 it was not uncommon to find it 60 mg. with enjoyment of good health. Many conditions other than those connected with the kidney influenced this content, and if the blood urea determination was the only test used mistakes would be made. If the blood urea was normal the condition of the kidneys could not be very bad. If there were 90 mg. of blood urea and a concentration of 2.6 to 3 per cent., it was safe to conclude that the cause of the condition was not kidney defect. He had tried the water test, but there was no evidence that it gave more information than did the urea test. A very important point was to deprive the patient of all fluid intake fifteen hours before giving the urea. With regard to the significance of albuminuria, it was fairly common in the young, and in them seldom led to any kidney disease later in life; casts were very seldom found in the urine of these overgrown, somewhat neurotic youths. When casts were found, even epithelial, should the case be regarded as grave? He had watched such cases for seven years, and, when they showed normal blood urea and urea concentration figures, no ill results had followed. Still, admittedly it was difficult to be certain whether a case of nephritis was being dealt with. In the absence of any obvious progressive deterioration in a few months, the conclusion was justified that there was no active renal lesion. Where, however, casts and blood were present, a more serious view should be taken, but even some of these cases cleared up entirely. It was of the utmost importance to examine the centrifuged deposit. As to the relationship of high blood pressure to nephritis, he had seen boys with a systolic pressure of 155 mm. and a diastolic of 80, with some albuminuria, and in several of them nothing further had happened. Some people's normal blood pressure was high compared with the average. When this high pressure was associated with cardio-vascular changes, it was common to find the kidneys also involved; when this happened the end was not very distant. There was no real treatment for established kidney disease; all that could be done was to place the kidneys under the best conditions to recover. Certainly in acute nephritis all that could be effectually done was to keep the patient warm and protect him in the usual way. In the cases in which the stomach was disturbed, he was in the habit of using 50 per cent. glucose, which enabled the patient to be supplied with a considerable number of calories daily. In the parenchymatous variety, with much oedema, no doubt a good solid diet containing a fair quantity of protein was beneficial. In this form there was a natural tendency to diuresis. He did not believe there was any evidence that protein did any harm in renal disease, and the patient's resistance and general health should be maintained as well as possible.

Sir THOMAS HORDER did not agree with keeping the number of renal tests as few as possible, in the present state of knowledge, and in view of the probability that nephritis was not an entity so much as an evidence of general metabolic disturbance. The symptoms, as well as the results of tests, must always be taken into account. With regard to the significance to be attached to the finding of casts, much depended on the criterion. If the urine were centrifugalized and casts were afterwards found, that must not be placed on the same basis as the finding of the doctor who, in a routine way, placed the urinary sediment under the microscope. Nephritis he regarded as a disease of very slow progress, if the patient succeeded in escaping infections—not necessarily grave ones, but such conditions as sore throat and coryza. He somewhat regretted that some impatience was nowadays shown over the slow recovery manifested by these patients. He agreed with Professor Maclean that a patient with parenchymatous nephritis whose disease had rendered him anaemic did better on a mixed diet. Active treatment of the condition known as chronic nephritis he regarded as the therapeutics of the future rather than of the present.

Sir JOHN THOMSON-WALKER spoke of the surgical aspect. He said that in the medical disease an immediate result was not looked for, as an almost permanent condition was being dealt with. In the surgical disease, however, in 80 per cent. of cases a temporary condition was being dealt with. A man with back pressure on the kidneys and an enlarged prostate would, in 80 per cent. of cases, recover his kidney function in ten days, without removal of the prostate, simply by bringing about efficient drainage. In borderline cases of nephritis treated surgically the good effect following decapsulation of the kidneys he attributed entirely to the incision. He agreed with Professor Maclean's desire to have the renal tests reduced to a minimum, and reaffirmed his own confidence in the urea tests rather than in the colour tests. Still the ordinary examination for urea in the urine must not be neglected; in many cases the special tests could be dispensed with on finding 2 per cent. of urea in the ordinary urine. The urea concentration test forced the kidney to work as high as it could be expected to work at any given time; it was important to know what the kidneys could stand. In the majority of cases on which he had operated for enlarged prostate or for a bladder condition the urea was less than normal, but that did not prevent his decision to operate. Only when half the kidney tissue was inactive was the blood urea test important; until then he did not think there was much accumulation of urea in the blood.

Sir WILLIAM WILCOX agreed that the two most important tests of renal function were the urea concentration test and the blood urea test; he pleaded for the adoption of another, which he regarded as important—namely, the estimation of the chlorides in the urine, calculated as sodium chloride. In cases of damage to the kidney, sodium chloride was found to be much below 0.5 per cent.; in waterlogged cases the chlorides were almost absent. He did not know of any disease in regard to which it was so difficult to give a prognosis as in kidney disease. He regarded kidney disease as analogous to such conditions as hay fever and asthma, and thought that in kidney disease there was a peculiar sensitiveness of the kidney tissue to some toxin. He appealed for more patience in treating cases of this disease; heroic measures were useless. The amount of blood urea he did not regard as indicating the intensity of the symptoms in a case, but it was useful in distinguishing kidney from heart cases.

Dr. J. W. McNEE also thought it would be unwise to reduce the number of renal tests in use, especially as those tests were crude; they should be of more advantage in surgical cases, which were instances of temporary renal insufficiencies. In performing these tests it must be remembered that the extrarenal factors counted for much; questions of amounts of previous diets, liver involvement, cardiac disability and failure were all important. The blood urea test was of very great value in watching the progress of a severe case of nephritis. He also used the urea concentration test, though sometimes it did not give the information needed. A third one he used was the

ater concentration test; it was easy to do, and had often applied the knowledge he wanted. He would be loath to give up any of those three tests, but he did not think anyone ought to be restricted to three. Sometimes, for instance, it was well to do a blood creatinin test, though it was not necessary as a routine. He had seen albuminuria with casts clear up in nine months. In regard to treatment, he thought the profession at the present day stood in need of guidance concerning the use of diuretics.

SURGICAL TREATMENT OF OSTEO-ARTHRITIS OF THE HIP.

At a meeting of the Buxton Medical Research Society on February 17th, Mr. HARRY PLATT, consulting orthopaedic surgeon to the Devonshire Hospital, read a paper on the surgical treatment of osteo-arthritis of the hip.

Mr. Platt said that it was now widely realized that rational surgical treatment must be based on a clear understanding of the mechanical significance of the essential pathological changes seen in the osteo-arthritic hip. The radiographic appearances, which gave valuable evidence of joint deformation, were at the same time misleading. Thus the osteophytic lip of the acetabulum, which was often a dramatic feature in the radiogram, was from a mechanical point of view of little moment. Pain and limitation of mobility in the early stages were due to the dense infiltration of the joint capsule, which became abnormally adherent to the femoral neck. Later the complete loss of cartilage from the femoral head and acetabulum brought two eburnated bony surfaces into apposition. This bone sclerosis extended deeply, and explained the complete failure of Nature's efforts to ankylose the disorganized joint. Although osteo-arthritis of the hip-joint was usually a monarticular affection, early changes were not infrequently seen on the so-called healthy side, and the possibility of a bilateral involvement after some years must always be carefully gauged when operative attack was contemplated. Surgical procedures could be divided into four distinct groups: (1) forcible manipulation under an anaesthetic; (2) limited operations for the removal of osteophytes, thickened capsule, and other formations; (3) arthrodesis (surgical fixation); (4) excision of the head of the femur.

Manipulation.—All that a forcible manipulation could accomplish was to stretch to a certain degree the thickened and infiltrated capsule, or even to detach partially the soft osteophytic lip around the margin of the hip socket. In the early stages an increase in the range of mobility, accompanied by lessened discomfort, could be obtained by such a method. This procedure was suitable for the very early osteo-arthritis of the hip in the active and robust individual. A careful choice of cases would prevent any untoward complications following a manipulation.

Limited Removal of Capsule, Osteophytes, etc.—The operation known as cheilectomy—removal of the acetabular rim—introduced some years ago, was first considered and its rationale examined. When it was realized that this osteophytic rim was not a definite obstacle to mobility in itself, cheilectomy in its limited sense was obviously an operation which could accomplish very little. But the excision of the osteophytic rim, combined with a free excision of the thickened capsule, was a procedure of very considerable value, and could be regarded in some measure as the open equivalent of a manipulation. This operation also could be employed only in a limited group of cases, but might well be adopted more widely as an alternative to the more drastic procedures still to be considered.

Arthrodesis.—Careful observation of a considerable series of osteo-arthritic hip-joints had emphasized the fact that most patients would be well satisfied with a painless, complete ankylosis of the joint in a useful position. Arthrodesis was therefore the pivotal operation in the surgical treatment of osteo-arthritis of the hip. As a technical undertaking there were certain difficulties; in the well advanced stage, removal of the eburnated bony covering from the femur and acetabulum so as to expose suitable cancellous surfaces was not an easy matter. The operation took a long time and was a fairly severe test of the

endurance of the patient. On the whole it was an operation to be reserved for the robust type of patient of middle age, and was only suitable in specially selected cases amongst older people.

Excision of Head of Femur.—This was a revival of the old classical excision of the hip-joint. It consisted essentially in removing the mushroomed portion of the femoral head, leaving a rounded stump of the neck which was thrust deeply into the acetabulum in the position of abduction. There was no interference with the acetabular surface. As part of the operation the great trochanter, which had been detached to allow easy access to the joint, was reattached to the femur at a lower level, thereby gaining a position of mechanical advantage. In this operation the retention of a certain amount of mobility was aimed at. In the speaker's experience the operation had proved suitable in selected cases of osteo-arthritis of the hip in older people. It was quite certain that by this method pain could be eliminated, and often a useful degree of mobility remained. In some cases the hip-joint stiffened up rapidly and the end-result was equivalent to an arthrodesis.

In conclusion, Mr. Platt referred to the bilateral hip-joint arthritis which occasionally accompanied spondylitis deformans (spondylose rhizomelique) and dealt briefly with the mechanical correction of the spinal deformity and the possibility of preventing the onset of ankylosis in such hip-joints.

Drs. C. W. BUCKLEY and J. E. HARBURN remarked that the disease was increasing, and that many cases which came under their care were far advanced and from a surgical point of view were almost hopeless, but received some benefit from the baths and waters. Dr. J. B. BERR's experience of forcible manipulation had been unsatisfactory. Dr. E. BRIDLE suggested that some method of diagnosis ought to be devised to distinguish monarticular cases from others.

LIGHT TREATMENT.

At a meeting of the Chelsea Clinical Society on January 19th, Dr. SEYMOUR PRICE in the chair, a discussion on heliotherapy was opened by Sir HENRY GAUVAIN.

Sir H. Gauvain said that artificial sunlight must not be confused with natural sunlight, for in the latter the question of the value of air treatment had to be taken into account. Many further tests of the real value of ultra-violet rays in the treatment of disease would have to be undertaken before the true value of the method could be estimated; but he felt that, as in the clinical value of cod-liver oil, clinicians had anticipated scientists, and it might well be that new discoveries as regards ultra-violet rays might be made which would confirm the favourable experience of them amongst clinicians. The mind as well as the body was affected by direct sunlight. Sir H. Gauvain thought that sunlight should be used as an adjuvant to other forms of treatment in cases of surgical tuberculosis.

Professor LEONARD HILL followed with an account of his scientific work at Hampstead, and mentioned the value of sunlight in producing pigmentation, and as a bactericide.

Dr. H. MACCORMAC pointed out that epithelioma of the skin was rare in Alpine guides, and this was explained by the fact that their skin was constantly exposed to the direct rays of the sun. He considered that ultra-violet rays were useful in many skin diseases, especially in cases of tuberculous affections. In psoriasis and acne vulgaris the beneficial effect of the rays was most marked; alopecia areata, also, in some cases had been successfully treated with these rays. He thought that there was some danger in the self-administration of light baths.

Dr. MURRAY LEVICK agreed with Dr. MacCormac as to the superiority of the mercury vapour lamp. It was not always advisable to produce too deep a pigmentation in the skin, and he drew attention to the use of these methods of treatment by unqualified people, and the danger to the public engendered by such treatment. He thought that much knowledge was necessary for the proper administration of light, and that there were risks about such treatment which should not be left to the layman.

Dr. HOWARD HUMPHRIS said that sunlight undoubtedly induced chemical changes in the blood, as, for example, an increase in the calcium and phosphorus content. Ultra-violet rays induced a fluorescence in the skin; this was followed by a leucocytosis, and possibly the bactericidal power of the blood was increased. Sunlight was analgesic, and thus sciatica and lumbago might be cured by its use. It was especially useful in cases of anaemia in young people, and acted as an excellent tonic in elderly people. Dr. Humphris claimed for sunlight that it did good even in serious disease of the alimentary tract.

CARCINOMA OF THE RECTUM.

At a meeting of the Section of Surgery of the Royal Academy of Medicine in Ireland on February 19th, the President, Mr. R. C. B. MAUNSELL, in the chair, Mr. W. E. MILES read a paper on carcinoma of the rectum.

Mr. Miles said he had treated 587 patients for this condition, and in 211 of these the disease had occurred between the ages of 50 and 60, with almost equal frequency in men and women. There was only one type of cancer of the rectum—adenocarcinoma; but three varieties of carcinoma were clinically recognized, which differed in malignancy—the papilliferous type, the adenoid type, and the colloid degenerative type. In the first type involvement of the glands was seldom found, and it was the least malignant type; even after a restricted operation it was not apt to recur. This type was, however, in the minority. The adenoid type was much more malignant; there was always infiltration, and only an operation which aimed at removing the vulnerable tissues would protect a patient against a recurrence of this type. The colloid type affected the connective tissues, and was the most malignant type of cancer, and practically always recurred, even after the most drastic operation, as the dissemination was so widespread. These three varieties of carcinoma might be met with in any part of the rectum. Referring to symptoms, he said that if attacks of alternating constipation and diarrhoea were waited for, a case might be missed which would otherwise be amenable to treatment. Sometimes these attacks did not occur until the disease was very far advanced and the position of the cancer affected their early or late appearance. An urgent symptom, however, was actual difficulty in obtaining an action of the bowels at all. Ampullary growths might persist for a considerable time before they produced enough symptoms for notice to be taken of them. In cases of cancer of the rectum, if the liver was involved, it might be taken for granted that the growth had penetrated the peritoneum, and that the case was inoperable. It was impossible to say how long these growths might exist without producing any symptoms; they might be present for six months before any symptoms showed themselves, but the extent of the circumferential involvement was an index of the depth of the growth, and of the length of time the disease had been present. The operability or inoperability of a case could not be estimated by digital examination alone. It was necessary to open the abdomen and see what the condition of extramural extension was. The dissemination of cancer from the extramural lymphatics was slight.

The President drew attention to the lack of symptoms in cases of carcinoma of the rectum, except when the growth was low down, near the anal canal, in which case the pain was very severe. As compared with Mr. Miles's figures, the operations for the condition which he (the President) had done were very small, but it was a condition of much importance in which he took great interest.

Sir WILLIAM TAYLOR said that anyone who had operated to any extent on cases of carcinoma of the rectum must have recognized that there was only one scientific method of dealing with the condition, and that was the combined abdominal and perineal procedure. He referred to the importance of opening the abdomen, and not estimating the operability or inoperability of a case by digital examination alone. On several occasions after opening the abdomen he had found secondary deposits in the liver which otherwise could not have been detected. If he passed his hand right above the liver he found secondary deposits, even though the under surface of the liver was absolutely

free from them. By the combined abdominal and perineal operation the disease could be removed in its entirety, and therefore that was the only satisfactory procedure. He drew attention to the small number of cases of carcinoma of the rectum seen in Ireland in comparison with the very large number seen by Mr. Miles at the Cancer Hospital in London, and said that from the comparatively small number of cases he himself had seen he had come to the conclusion that six cases were inoperable for one that was operable. When at the Mayo Clinic recently he had seen six cases operated on in two days, by the parasacral procedure, after a preliminary colostomy; by this method he believed the mortality rate was about 5 per cent. Now, however, the operation done at the Mayo Clinic was the combined abdominal and perineal one. His own personal death rate from this method was one out of fifteen cases.

Mr. SETON PRINGLE said that his mortality rate in these cases was much higher than those of Mr. Miles and Sir William Taylor. He mentioned a few points in his own technique which differed from that of Mr. Miles. Instead of opening the whole lumen by colostomy he only put in a small suture, and by this means it was possible to administer any quantity of saline to the patient immediately after the operation. He quite agreed that there was only one really radical operation for carcinoma of the rectum, and that was the combined abdominal and perineal one; although the mortality might be high, the patients who survived had a reasonable chance of permanent recovery.

Mr. H. F. MACAULEY thought the vast majority of cases of carcinoma of the rectum seen in Dublin were inoperable; he frequently found nodules in the liver, and this prevented further operation. There seemed to be no possible safeguard against recurrence in the liver.

Mr. H. S. MEADE in the last ten years had seen 46 cases of carcinoma of the rectum, and of these 26 were inoperable; 11 patients, though operable, refused operation, because they had had a colostomy. Of the rest, 2 were still alive, and were receiving deep x-ray treatment. He had operated on 20 cases, and in the first 8 he had done the perineal operation, and they were all dead except one. By the combined abdominal and perineal method he had operated on 12 cases, 7 of whom had died, but the other 5 were still alive.

Mr. MILES, replying, said that he was pleased to hear that in Dublin the combined abdominal and perineal method was gaining ground, for he was quite confident that it was the only method which was really successful in these cases. If the disease was extensive the operation was futile; it should be limited to the earliest possible cases if it was desired to prevent patients from a recurrence. It was without value if an actual growth was present in the perineum. Even in early cases the biggest possible operation only gave a possibility of preventing recurrence of the disease. In all obstructive cases he performed caecostomy. In a toxic patient there was danger of chronic obstruction if the bowel was divided, so he drained through the caecum.

At a recent meeting of the Royal Medico-Chirurgical Society of Glasgow, the President, Professor ARCHIBALD YOUNG, in the chair, two communications were made on the subject of trigeminal neuralgia. Mr. GEORGE DALZIEL showed three patients who had been treated by the injection of alcohol. The technique employed followed that described by Dr. Wilfred Harris, but in each case only the third branch was injected, the results being very satisfactory. Mr. JAMES R. LEARMONTH read a paper on neuralgias of the head and their treatment. Using the term "neuralgia" in its wider sense, he considered first, in general, the conditions which might give rise to pain referred to the various cervical nerves. Pain referred to the fifth nerve was then discussed in some detail, special reference being made to the methods of treatment adopted for the relief of trigeminal neuralgia. A plea was made for the earlier resort to operative measures—the procedure of choice being division of the sensory root of the fifth nerve between the ganglion and the pons. This operation gave instant and lasting relief at a cost of permanent anaesthesia in the distribution of the nerve.

The operative technique, which was briefly outlined, was that employed by Dr. A. W. Adson, neurological surgeon to the Mayo Clinic. In conclusion, the speaker referred to the rarer forms of neuralgias associated with the seventh through the geniculate ganglion and with the glosso-pharyngeal nerve. In the discussion which followed Professor Young, Dr. Jones, Mr. William Rankin, and Mr. J. Scouler Buchanan took part.

JAMES MACKENZIE INSTITUTE.

In a paper on the Schick test, read before the James Mackenzie Institute for Clinical Research, St. Andrews, Dr. MATTHEW FYFE referred first to the incidence and death rate of diphtheria and to the expenditure incurred by isolation and treatment. By the use of the Schick test during an epidemic, he said, it was possible to detect susceptible contacts, who could then be temporarily immunized by antitoxin. When time permitted toxoid antitoxin could be employed to produce a more lasting immunity. He described the passive immunity, apparently derived from the mother, of newborn infants, the gradual loss of this in the first two years of life, and the gradual development of acquired immunity after puberty, and he emphasized the high incidence and death rate of diphtheria from the second to the tenth years of life. The value of the Schick test as a check on vague bacteriological reports and as an aid in the identification of carriers was illustrated, and its simplicity, cheapness, and safety were emphasized. Dr. Fyfe, in conclusion, referred to the results of immunization of Schick-positive subjects in other countries and in institutions and public health areas in Britain. He looked forward to a time when, by a general adoption of those methods, diphtheria would be banished from the list of common diseases dangerous to life.

Reviews.

THE CHEMISTRY OF DRUGS.

Mr. NORMAN EVERS, in the preface to his book *The Chemistry of Drugs*,¹ states that his object has been to give a description of the substances used in medicine from the standpoint of pure chemistry. The author only touches incidentally upon the therapeutic action of drugs, but gives a concise description of the chemical constitution, the reactions, and the chemistry of the methods of manufacture. The book deals with the chief synthetic drugs and with all the naturally occurring drugs of importance in medicine whose active principles are known. The treatise is therefore written primarily for the chemist, but it is of interest to all concerned in the study of the action of drugs. It is the first time that this information has been collected into a single volume, at any rate in this country, and the book has the great advantage over foreign works of somewhat similar scope in that the author has exercised his powers of selection and has given an account only of those drugs which are of real importance in medicine.

The volume deals with the following classes of drugs: synthetic drugs; alkaloids, glucosides, and other vegetable drugs; and drugs of animal origin.

In the case of each an account is given of the source of the drug, its chemical properties, its reactions, and the methods of manufacture. The chapter on drugs of animal origin is of particular interest, since it contains an account of the chemistry of cod-liver oil and its vitamins, and of various internal secretions, notably insulin, adrenaline, and thyroid. Most of this chapter is concerned with discoveries made during the last few years, and it is interesting to note how rapid has been the advance in knowledge of the chemistry of the internal secretions.

The standard methods of manufacture of insulin are described, and in this chapter the author has included a note on the work of Collip on the parathyroid gland, carried out during the past year. In an appendix Mr. Evers writes a few pages on the relation between chemical

constitution and physiological action. He wisely concludes that we have probably only touched the fringe of this vast subject, but draws attention to the interesting fact that hitherto all efforts to improve the therapeutic properties of naturally occurring drugs have been almost completely fruitless. He points out that "it can hardly be a coincidence that in so many cases these compounds produced in plants, perhaps as waste products, should of all their derivatives so far studied have the maximal physiological action in the body."

In the introduction the author is severely critical of English therapeutics, contending that "there is an undoubted contrast between the amount of scientific ingenuity and intelligence which has been applied on the chemical side to the production of new synthetic drugs, and the haphazard methods employed in their clinical use and trial." He goes on to express the opinion that successful advertising methods play a wholly disproportionate part in influencing members of the medical profession in their choice of drugs. One cause of this state of things is, the author maintains, the absence of any organization in this country for providing an impartial test for the pharmacological and clinical properties of a new drug. In defence of the medical profession, it must be pointed out that it is much more difficult to determine the therapeutic properties than the chemical properties of a drug. Even when allowance is made for this fact, however, there is still a marked contrast between the mass of exact knowledge regarding the chemical properties of drugs collected by the author in this book and the scrappy and inexact information that alone is available regarding the comparative therapeutic value of drugs.

A CYCLOPAEDIA OF PATHOLOGICAL ANATOMY.

PROFESSORS F. HENKE of Breslau and O. LUBARSCH of Berlin are producing a series of monographs on pathological anatomy and histology. When the series is complete it will comprise some fourteen or fifteen volumes. So far the second and sixth have been received in this country.

The authors, with the aid of numerous collaborators, have set themselves the task of collecting all the knowledge which is available on the morphological aspects of disease. They have confined themselves almost entirely to the anatomical aspect, though recognizing that pathology, like all the other biological sciences, has advanced into a territory where new methods and outlook often make pure morphology appear rather old-fashioned. They have met this criticism by insisting that morphology still has a large part to play, and that no extensive series of monographs written from this standpoint alone has yet appeared. They express the hope that these large volumes, each of which is copiously illustrated, will prove that German medical science, despite lack of money and other difficulties, shows no slackening of effort, and is still indispensable to the whole world of medical science.

The second volume contains the morbid anatomy of the diseases of the heart and blood vessels. The first portion of this (179 pages) is devoted to malformations of the heart; then follow diseases of the endocardium, of the musculature, the bundle of His, and finally the diseases of the pericardium. The whole occupies 606 pages.

The description of the malformations of the heart illustrates extremely well the value of morphology and also its limitations. It gives a catalogue of the forms assumed by the various anomalies, suggests the factors at work and the time at which they act in producing the various lesions. To get any further it is necessary to leave purely static considerations, and to take into account the factors of growth responding to dynamic influences.

Considerable space is given to the work of Beneke, who in the last ten years has attempted to explain first the normal development of the heart, and then its malformations, on hydrodynamic considerations. His view is that the form of the heart tube is the result of the

¹ *Handbuch der speziellen pathologischen Anatomie und Histologie*. Herausgegeben von F. Henke und O. Lubarsch. Zweiter Band: Herz und Gefässe; und Sechster Band: Harnorgane, Männliche Geschlechtsorgane. Erster Teil. Berlin: Julius Springer, 1924 und 1925. (Sup. roy. 8vo. Bd. II, pp. xii + 1152, 232 figures; paper cover G.M.80, bound G.N. 92.40. Bd. VI, pp. viii + 792, 334 figures; paper cover G.M.81; bound G.M.85.75.)

¹ *The Chemistry of Drugs*. By Norman Evers, B.Sc., F.I.C. London: Ernest Benn, Ltd. 1925. (Cr. 6to, Pp. viii + 247. 3s. 6d. net.)

blood stream flowing through it, just as a straight blood vessel of uniform bore is the product of the blood stream flowing through it. The auricles are thin because they function as a reservoir containing only a slowly moving stream of blood, while the ventricles bring about a much more rapidly moving stream of blood. Septa are formed from adjacent heart tissue wherever, owing to the "steady stream" influence, there are produced lateral surfaces free from pressure. The interatrial and the interventricular septa arise in this way. Similarly the spiral septum forms in the intermediate space between two different columns of blood. Another factor is the varying demand of different tissues for blood. For instance, the brain, which grows rapidly when compared with the trunk, occasions great changes in the formation of the aortic arches. The case could, indeed, be greatly strengthened by taking into account the successive stages in the development of blood vessels as revealed by the injection method. All recent work on the vascular system emphasizes the importance of hydrodynamic considerations. If the blood flow fails then the muscular development and the formation of the blood vessels is held up, the steady stream influence is only a feeble affair, and so the formation of heart valves, etc., is hindered. Since the fundamental factor is the blood stream it follows that the effect of anomalies of the heart will be widespread, and will affect many parts whose differentiation follows the normal development of the heart.

Whatever may be the outcome of these ideas of Beneke there can be no doubt that they are the most fruitful suggestions so far made for the understanding of the malformations of the heart. They fall into line with the Roux school of "Entwickelungsmechanik." The method of experimental embryology, owing to the fact that it is confined practically to amphibia and birds, is liable to severe limitations in unravelling mammalian anomalies, but nevertheless offers a field in which these hydrodynamic considerations can be tested. No answer is furnished in this monograph as to why these cardiac anomalies are more frequent in the male sex.

The chapter on the special muscular system of the heart is of great interest. There are still a large number of problems awaiting solution there. The author of this chapter seems to believe that there is no direct connexion between the sino-auricular node and the atrio-ventricular node, yet accepts the position that around the great veins in the interatrial septum and on the posterior surface of the right auricle there is an abundance of a specialized muscular tissue which resembles very closely the Purkinje tissue, but yet affords no direct path between the nodes. Again, he seems to be fascinated by the idea that the bundle of Purkinje is a sort of neuro-muscular termination, and is a region where nerve transforms itself into muscle. There is, however, no real evidence for such an idea.

The rest of the second volume is devoted to the diseases of the blood vessels. Like the preceding, it gives a most detailed account of all investigations bearing on the structural side of the special pathology of this system. The illustrations, often in colour, are numerous and excellent. The chapter on arterio-sclerosis is conventional, and is not nearly so suggestive as the recent review by MacCallum. There is a copious bibliography.

The sixth volume deals with special pathology of the urinary system. It contains first a consideration of the developmental anomalies of the kidney and the ureter; the illustrations of these are particularly noteworthy. Congenital hydronephrosis is illustrated by three figures—one showing a valvular deformation of the ureter, a second the effect of an abnormal renal vessel, and a third a high implantation of the ureter. The remainder of this volume deals with the diseases of the kidney, and though presenting no original features it is distinguished for the excellence of the figures illustrating the morbid histology of the kidney.

These monographs will form an important work of reference, for they are intended to bring present knowledge of morbid anatomy together under one cover. The excellence of the figures will make the series extremely useful to those needing illustrations of particular diseases, and the copious bibliography will be valuable.

TREATMENT OF FRACTURES IN GERMANY.

It appears that in Germany, as in England, all is not quite at the best in the treatment of fractures, and Professor FRITZ LANGE has laudably undertaken to try to improve matters in general, and particularly in country practice.* He holds that specially difficult and complicated cases should be sent to orthopaedic hospitals, and he confines himself therefore to directions as to the treatment of the ordinary forms of bone injury. Consequently no mention is made of the various plating operations, and only in one instance—that of fracture of the os calcis—is any penetration of the skin by surgical means advised. Professor Lange speaks of the number of cases of knee ankylosis from septic synovitis which he saw during the war and attributed to the use of nail extension, and he excludes this method from his recommendations, confining himself to splints and to gypsum and extension by means of the zinc-gel bandage, which he has found much more trustworthy than adhesive plaster, Heussner's glue, or mastisol. But the elaborate screw corrector which he recommends for the treatment of fractures near the ankle-joint is hardly likely to form part of the country practitioner's armamentarium.

The usual typical fractures are described and illustrated, and methods of treatment clearly set forth. We do not look in a German work for any appreciation of British surgery, but we must confess to being very much surprised that a surgeon of Professor Lange's eminence should be so ill informed as he shows himself to be in the surgical history of the late war. The only reference in this book to the Thomas splint is to be found in the following passage (p. 81):

"The mortality of gunshot fractures of the thigh among the French and English amounted in the beginning to 80-90 per cent. As soon as the Americans, however, took part and instituted special gunshot-fracture hospitals under the direction of American orthopaedists, the mortality fell to 10-15 per cent. For this improvement American military surgery has to thank the superior education of their surgeons at the university. In America for the last twenty-five years orthopaedics have been a subject for examination, and consequently every medical man is obliged to improve himself orthopaedically. And the Americans, moreover, brought with them a transportation splint, the Thomas splint, which indeed does not altogether represent an ideal splint, but, however, was actually better than the Volkmann splint and the lath-bandages (*Lattenverbände*) which were most used on the German side."

It would be difficult, we think, to crowd more misstatements into so short a passage. The history of the Thomas splint and the achievements of Sir Robert Jones and his coadjutors, long before the first American ambulance approached the battlefield, and Maurice Sinclair's work too, seem all to be unknown in Munich.

This book is well printed and the illustrations are excellent, and its low price may well make us envy our German brethren, who have instruction placed at their disposal at a price within the reach of all. Such a book could not be published in Great Britain for less than two or three times the German price.

UNIVERSITY REFORM IN LONDON.

EVERYONE who has given attention to the subject will accept the dictum with which Mr. H. G. WELLS opens his introduction to Mr. HUMBERSTONE's book on *University Reform in London*,† when he says that "a university stands not for material but for mental interests." Nevertheless, most readers acquainted with the recent history of the University of London will turn first to the chapter on the site question, because at the present stage the party in university politics to which the writer belongs is indicated by his attitude towards this matter. Mr. Humberstone, though formerly a student of the Royal College of Science, is all for the Bloomsbury site. This site is of 11½ acres immediately north of the British Museum. The offer to present it to the university was

* *Die Behandlung der Knochenbrüche durch den praktischen Arzt.* Von Geh. Hofrat Professor Dr. Fritz Lange. Klinische Lehrkurse des Münchener medizinischen Wochenschrift, Band 6. München: J. F. Lehmann. 1925. (Med. 8vo, pp. 124; 81 figures. Paper cover, M.3.50; bound, M.5.)

† *University Reform in London.* By Thomas Lloyd Humberstone, B.Sc.Lond. With an introduction by H. G. Wells. London: G. Allen and Unwin, Ltd. 1926. (Post 8vo, pp. 132; 4 plates. 7s. 6d. net.)

definitely made by the then Minister of Education, Mr. H. A. L. Fisher, as long ago as April, 1920. The Government was prepared to secure the university against loss on maintenance charges, though not to provide the cost of the buildings out of public funds. The university, with its curious faculty of looking a gift horse in the mouth, has not accepted the offer, although, as Mr. Fisher said in January, 1925, "An American university presented, as was the London University, with the superb site of eleven acres in the heart of a capital city, would not have deliberated for a moment whether the site was worthy of acceptance, but in the space of an incredibly small number of months would have covered it with magnificent buildings, and would then have asked for more."

Discussion of the subject has become mixed up with the proposal to remove King's College from the Strand to Bloomsbury. The Government offered £375,000 to King's College if it vacated the site in the Strand. It is comprehensible that King's College might see no advantage in moving from the Strand to Bloomsbury, and might fear that the grant it was to receive for surrendering its present site would not be large enough to prevent it from falling into financial embarrassments before it could re-establish itself on the new site; and it can also be understood that it might have been actuated by a fear that it would by removal lose some of its individuality and traditions. The conclusion does not follow that "if King's College declines to shift, the whole Bloomsbury scheme must fail," to quote the words of Dr. Graham Little, the representative of the university in Parliament; nor does the commission's conclusion that the removal of King's College is a condition precedent to the formation of a university quarter in Bloomsbury. As Mr. Humberstone says, apart from King's College, the whole of the area available in Bloomsbury could be profitably used in course of time for university purposes.

His book gives a convenient, and on the whole very impartial, summary of the circumstances in which the numerous commissions on the subject were appointed and of their recommendations. The matter is once again in commission, the report of the Haldane Commission having been referred to a departmental committee of the Board of Education, which is instructed to recommend what changes are most needed in the existing constitution of the university. The present chairman is Mr. Hilton Young, M.P., and for the first time the university itself is strongly represented, the members including graduates (Sir Robert Blair and Dr. Eason), teachers (Mr. Lees Smith and Professor A. F. Pollard), and the late Principal, Sir Henry Miers; the other members are Sir A. Selby-Bigge, late Secretary of the Board of Education, and Miss K. Wallas. It is believed that the report of this committee will not be long delayed. Mr. Humberstone's book will form a useful preparation for an intelligent appreciation of its recommendations.

AIX-LES-BAINS AND FIBROTIC ARTHRITIS.

TITLES of books are sometimes disappointing in promising more than the text fulfils, and, indeed, being the best part of the publication; conversely, they may be deceptive in not revealing the full value of the contents. It is to the second class that Sir JAMES KINGSTON FOWLER's recent *Aix-les-Bains and Mont Revard: The Douche Massage Treatment of Arthritis and Fibrositis*¹ belongs, for the title page might suggest that it is but one more of the familiar objects on a waiting-room table, extolling the virtues of a hungry spa.

Besides giving a pleasant, practically useful, and "non-guide-booky" description of Aix-les-Bains and its attractive station for an after-cure, Mont Revard, which has undergone much change for the better accommodation of visitors, the author deals with the nomenclature of rheumatoid diseases, classifying these affections as fibrositis, accepted with the commendation "a perfect name, and one the use of which should be encouraged," fibrotic or fibrous arthritis causing partial or complete fibrous ankylosis, of which he gives a rather dramatic

account in the body of a dead senior colleague at the Middlesex Hospital, who left his ankylosed elbow-joint to the museum so that future generations of students might profit from his bodily infirmities; unfortunately, before the specimen was secured at the necropsy, peri-articular adhesions were broken down and there was nothing to show in the joint; the other forms described are synovial arthritis and osteo-arthritis. Little is said about the etiology of rheumatoid or fibrotic affections, but between the lines there lurks some suggestion of scepticism about dental sepsis and its drastic treatment.

Believing that the aim of the teacher should always be to crystallize the substance of his instruction into a short sentence, an *obiter dictum*, Sir James Fowler practises this with eminent success, and the personal touches add charm to his common sense. The illustrations and get-up of the book are admirable, and as all his writings provide most pleasant reading we look forward to his promised *Notes and Queries of a Physician*.

THE TOKYO INSTITUTE FOR INFECTIOUS DISEASES.

THE third volume of *Scientific Reports of the Government Institute for Infectious Diseases* at the Imperial University of Tokyo contains nineteen papers on bacteriology, pathology, chemistry, and medical entomology. Some of these are in English, others in German, and one in French. The volume deals with the year 1924. Among the articles dealing with bacteriology is one which describes a new method of staining the flagella of bacteria. If other workers find this as easy and are as successful as the inventor, he will be credited with having made an important contribution to bacteriological technique. In the same section, in an article on how the antitoxic immunity is transmitted into the system of a newborn child through lactation, another author reports experiments which lead him to deny the heredity of acquired immunity. He thinks that immune bodies in milk can be absorbed unchanged from the digestive organs of a newborn child if the bodies are from the homologous animals, but not from animals of other species. Colostrum is very rich in antibodies, and one of its main functions is to equip the newborn infant with maternal antibodies and thereby adapt it for the environment of the outside world.

The section on pathology contains an article on the influence of the constituents of thymus gland cells on the growth of the young, and an experimental study of the secretion of bile. Both of these are well documented reviews and neither appears to have been published previously.

Japanese workers have recently been devoting much attention to the functions of lymphocytes, and the present volume includes three articles on this subject—one dealing with the biochemical action of lymphocytes, another with the significance of the germinal centre of lymph follicles, and a third with the function of the lymphocytes in the intestinal tract. Many of the other articles which we have not mentioned are concerned with diseases not met with in this country, but important in Japan.

SUNSHINE AND OPEN AIR.

FOR those who are as yet unacquainted with Dr. LEONARD HILL's admirable treatise on *Sunshine and Open Air* the second edition² is now available. The fact that the first edition (reviewed in these columns on August 9th, 1924, p. 237) was published less than eighteen months ago is indicative of the interest displayed in this very important subject. The herding together of the population in towns, where sunshine and fresh air are none too plentiful, has rendered a scientific and ordered knowledge of these indispensable therapeutic agents essential to the medical practitioner. This knowledge will be found in compact form, and without irrelevant detail, in Dr. Hill's book.

The work is primarily concerned with the influence of sunshine and open air on health, and has special reference

¹ *Aix-les-Bains and Mont Revard: The Douche Massage Treatment of Arthritis and Fibrositis*. By Sir James Kingston Fowler, K.C.V.O., C.M.G., M.D., F.R.C.P. London: William Heinemann (Medical Books), Ltd. 1925.

² *Sunshine and Open Air: their Influence on Health, with Special Reference to the Alpine Climate*. By Leonard Hill, M.B., F.R.S. Second edition. London: E. Arnold. 1925. (Demy 8vo, pp. vii + 132; 12 figures, 7 plates. 10s. 6d. net.)

to the Alpine climate; but it is wider in scope than its subtitle would suggest, and includes much related matter. After a section treating of the atmosphere at high and low altitudes and its geographical variations, there is a chapter on humidity and catarrh which discusses at length the effect of breathing warm, moist stagnant air. There follows a detailed consideration of sunshine, its analysis, its effects, its distribution, its comparison with the mercury vapour lamp, and so forth. The biological action of light occupies Chapter IV. Here are discussed such important matters as penetration; action on the blood; deficiency diet, rickets, and light. The last chapter deals with metabolism and cooling power, and shows the differences between these processes in England and the Alps. There is an appendix on artificial light treatment. Altogether a valuable and interesting book.

NOTES ON BOOKS.

THE thirty-sixth edition of *Burdett's Hospitals and Charities*¹ shows an important change, as compared with previous editions, tables of comparative hospital statistics being now omitted, with the exception of those relating to the large funds. The introductory chapters contain particulars of these funds, and also descriptions of the St. Marylebone Hospitals League, which was founded in 1923 to support the ten great hospitals in the borough, and of the Sheffield Joint Hospital Board. Other chapters deal with the contributory scheme of the Hospital Saving Association, the Rockefeller Foundation, the London School of Hygiene and Tropical Medicine, the Charity Organization Society, the Jewish Board of Guardians, and the Association of Nursery Training Colleges. In this edition appear also for the first time particulars of the hospitals of the Sudan Medical Service, and the statistics of the Indian military hospitals have been brought up to date. The part of the volume containing the directory of medical and nursing institutions has been carefully revised, and the great mass of information in it renders the present issue an indispensable reference book for all concerned with medical charity.

The thirty-fourth edition of the Charity Organization Society's *Annual Charities Register and Digest*² continues on the lines which have rendered its predecessors so valuable to all concerned with charitable work in London. The importance of the index is fully recognized, over sixty pages being devoted to it, and the details of the various societies and charitable agencies are kept well up to date. In a preliminary review of the year a general account is given of the finances of the metropolitan charities, and in the appendix to the volume are included such different organizations as friendly and trade societies, metropolitan savings banks and employment exchanges, hospital almoners, and agencies for the homeless.

Professor CHARLES ACHARD, the accomplished Secrétaire-Général of the Académie de Médecine, has published five lectures on diabetes³ which deal respectively with the utilization of sugar, clinical investigation into failure of the organism to utilize sugar in many different conditions, metabolic disorders in the course of diabetes, and insulin. Diabetes mellitus is regarded as a metabolic disturbance arising in the course of various disorders, a syndrome common to a number of morbid conditions, and not itself a disease. There are some interesting observations on the lipase content of the blood in diabetes and in other conditions, and the action and therapeutic uses of insulin are fully described in a book which, though small, contains many references and shows the learning and wisdom of the author.

The work of Dr. LEROUX-ROBERT on the value of high frequency in oto-rhino-laryngology⁴ has a preface by Professor D'ARSONVAL, who describes his first introduction of the method at the Hôtel-Dieu in 1896 and its cold reception. The author gives a full description of the various forms of apparatus and appliances employed. The surgical use of diathermy—or, as he insists it should be correctly called, diathermo-coagulation—is well known in this country. He lays emphasis on the medical uses of diathermy, "rénovatrices," in contrast to the surgical uses, which are "destructrices." Both the medical and surgical applications comprise several

different methods of employing the agent, and the author gives the indications and technique with much precision. The diagnostic diathermy of Kubo for testing the labyrinth is described also. It is scarcely probable that there is such a panacea as Dr. Leroux-Robert would have his readers believe diathermy to be; but, making due allowance for his natural enthusiasm, he is to be congratulated on the account he has given of an agent which merits more attention than it has yet received at the hands of otologists and laryngologists in this country, at any rate in its medical aspect. It can only be by a much extended trial that the limits of its application can be precisely defined.

Modestly concealing his name under the pseudonym of "M.R.C.S.," a member of our profession reveals a real talent for verse in *Odds and Ends*.¹¹ Twenty out of the fifty short poems deal with the period of the war, and breathe a pathos in the graceful lines that, as the verses "After" beginning—

After the fear is forgotten,
The doubt of the dolorous days,
When anguish has faded to interest,
And 'tis mainly the crippling that stays,

sometimes recall Swinburne's musical lilt. Some of the other verses date back to the early eighties and Cambridge, while later ones were begotten in Exeter or—

Down away in Devon, where the ships go sailing by,
Where the dappled clouds in summer-time steer
eastwards up the sky,

of which there is a charming photograph of the rocky coast in sunlight as the frontispiece to this collection.

An account has been published of the proceedings of the special congress held at Berlin in April last year to consider nerve massage and allied conditions.¹² During the congress the use of nerve massage in the treatment of trigeminal neuralgia, and disorders of the sense organs, vasomotor system, and kindred conditions was considered, and some of the papers read are given in full. The volume also contains a report of the subsequent meetings in September and October, which dealt with the physiology and pathology of the peripheral nervous system.

PREPARATIONS AND APPLIANCES.

Apparatus for the Intravenous Administration of Saline. Dr. R. H. DUNLOP (Edinburgh) writes: The following is a description of an apparatus and technique for the intravenous injection of saline solution which I have designed to eliminate the disadvantages of the jug and funnel method.

The apparatus is sterilized (without risk of breaking the container) by submerging it in tepid water, which is then gradually heated to boiling point. The saline solution is heated to 40° C. and transferred to the container, which, after replacing the cork, is suspended in an inverted position. The temperature to which the saline must be raised will vary with each apparatus according to the length of the rubber tube E, as it is desirable to have the saline emerging from the intravenous needle at body temperature.

The container having been suspended at a height of from 2 to 3 feet above the table on which rests the arm of the patient, the clamp F is released and the solution allowed to flow until all air is expelled from the system. A tourniquet is applied to the patient's arm and the skin at the bend of the elbow is sterilized by application of ether and iodine. The syringe is held in the right hand and the needle introduced into a prominent vein. Provided that the rubber tube E is clamped, blood will flow into the syringe on withdrawing the piston if the vein has been entered. When blood appears the tourniquet is loosened and the clamp released; the saline solution will then pass into the vein. During the operation the U-bend of the air inlet tube contains a small quantity of saline which by its constant movement serves to remove impurities from the air entering the container, and as an indicator of whether or not the saline is flowing.

The advantages of the apparatus and technique are that it is simple, and an air lock is impossible; the saline solution is not contaminated and it is administered at body temperature throughout the operation; less time and no assistance are required, and the vein is secured without incision.

The apparatus can be obtained from Arch. Young and Sons, 57, Forrest Road, Edinburgh.

TREATMENT OF CANCER BY LEAD.

MEMORANDUM BY THE LIVERPOOL RESEARCH COMMITTEE.

FROM time to time as opportunity served we have published notes of the work being done by the Cancer Research Committee established in Liverpool a few years ago for the investigation of the treatment of cancer. Dr. W. Blair Bell, professor of obstetrics and gynaecology in the University of Liverpool, has been the moving spirit, and is now honorary director. His position is fully defined in the memorandum by the committee published below.

The research has been wholly or mainly directed to the administration of lead in colloidal form, and the results in a certain percentage of cases reported have been strikingly favourable.

The chairman of the committee, which is mixed lay and medical, is Mr. J. A. Smith, the honorary treasurer Mr. Rex D. Cohen, and the honorary director, as already said, Professor Blair Bell. The members of the committee are: Dr. J. G. Adami, F.R.S. (Vice-Chancellor of the University of Liverpool), Sir Robert Jones, K.B.E., Ch.M., F.R.C.S., Mr. C. Sydney Jones, Mr. F. T. Paul, D.Sc., F.R.C.S., Mr. J. J. Shute, Mr. J. A. Smith, Mr. R. Wilson, and Mr. B. Crompton Wood, M.P. Communications should be addressed to the Secretary, Cancer Research Committee, The University, Liverpool.

Memorandum of the Liverpool Cancer Research Committee.

It may be held to be wise to ignore criticisms that have no basis in fact. Nevertheless, the spread of adverse criticism creates rumours, and from our war-time experience we know how damaging rumour may be both to morale and to the pursuit of proper procedures. For this reason we consider it expedient to inform the medical profession of the truth of certain matters concerning which grave and unjustifiable charges have been made.

These charges are of two kinds:

I.

It has been stated that some great secret has been withheld from publication; that is to say, the method of preparation of the material used has not been disclosed. Now, in spite of the fact that Professor Blair Bell would have been absolutely justified, and would have received the entire support of this committee, in withholding publication on this matter in view of the manifold difficulties of manufacture and the dangers of usage, as so ably explained by Professor Carter Wood in the *Lancet* (1926, i, 414), in point of fact this course has not been adopted. So long ago as February, 1924, Professor Blair Bell described and discussed the method of preparation of colloidal lead. Since that time many variations have been employed, but the general method has remained the same. The dosage and all the dangers and difficulties have likewise been published. Finally, however, has not even yet been reached.

The very fact that the general body of practitioners appears to be ready to use the material if it be distributed without control, to the possible disparagement of the method and serious risk to the public, has impelled the committee recently to protect the method of manufacture, as was done in the case of insulin.

II.

With the dissemination of such erroneous ideas it became inevitable that many would charge Professor Blair Bell with "making hay while the sun shines," and say that he is keeping the treatment in his own hands, is exacting exorbitant fees, and is rapidly amassing a fortune by the employment of what to all intents and purposes they assert is a secret remedy.

This charge is wholly contrary to the truth.

The Liverpool Cancer Research Committee has evidence that during the first five years 75 per cent. of the 200 odd patients treated were virtually charity patients, some few paying a nominal fee for accommodation, the majority being treated free of all cost. In other words, during the first five years since the initiation of the treatment Professor Blair Bell has received remuneration from at

most 75 patients—that is, an average of 15 each year. Nor, considering the benefit conferred, can the remuneration be regarded as other than most moderate.

Feeling acutely the charges circulated against him—often by men he had regarded as friends—at the end of four years a cheque for the whole amount charged for treatment was sent by him to the Cancer Research Committee. This cheque the committee refused to accept. At the end of last year, on his return from America, when, for the first time, there was a large influx of patients, Professor Blair Bell approached the Cancer Committee again, asking them to receive all the fees for treatment, at the same time becoming themselves responsible for all necessary expenses. Knowing how gravely his intense preoccupation with cancer had interfered with his gynaecological practice, the committee would not consider this offer. They made the counter-offer, which has been accepted, that for his services as director he should, from December 1st, 1925, receive a stipend like the rest of the staff. In return the committee assume all responsibilities for the housing and maintenance of the cancer patients under Professor Blair Bell and the clinical staff; they receive all the fees, and place all the books detailing income and expenditure under the weekly supervision of a well known accountant. They have taken under their control the nursing home previously occupied by Professor Blair Bell's gynaecological cases, and have, in addition, bought and furnished another. Out of the moneys received they are continuing the stipends of those of the staff engaged in research, and are enlarging that staff, and they have by resolution agreed that all moneys over and above those expended as aforesaid shall be devoted to the furtherance of medical research.

We may add that these arrangements have been submitted to the President of the General Medical Council, and have received his personal approval. Further, to secure its position, the question of incorporation is being considered by the committee.

It is felt by all engaged in this work that, if it can be generally known that Professor Blair Bell and the clinical staff are not benefiting to any unusual degree by this work, but are by their labours supporting the entire burden of the laboratories and clinical organizations, there may be greater confidence in, and greater sympathy with, what promises to develop into a very wonderful advance in the treatment of a most terrible state.

We append a copy of the circular letter which has been drawn up and sent by the director to all doctors who have written to ask for treatment for their patients.

Signed, on behalf of the Liverpool Cancer Research Committee,

J. A. SMITH, Chairman.
REX D. COHEN, Treasurer.
J. GEORGE ADAMI.

Liverpool, Feb. 23rd, 1926.

CANCER RESEARCH COMMITTEE.

Dear Sir,

Thank you for your letter. You will understand that we are engaged in a scientific investigation, and have regarded our clinical work as a test of the findings obtained in the laboratory. We do not pretend and never have pretended that we have a "cure for cancer." Nevertheless, the ultimate aim of all such work is that, and we are prepared to take suitable cases that can come for consultation in the first instance, provided they are fully informed:

- (1) That consultations are arranged in order that it may be determined whether the case is suitable for further investigation. A consultation does not mean that *ipso facto* the patient will be taken for treatment.
- (2) That the treatment itself may be dangerous.
- (3) That the treatment is experimental in nature.
- (4) That there is no guarantee whatsoever as to the result.
- (5) That patients must, if they come, place themselves unreservedly in our hands, and continue the treatment so long as we think it advisable.
- (6) That accessory treatment, such as x rays and operation, may be necessary.
- (7) That, if an operation has been performed, a section must be sent in advance.
- (8) That all fees are handed over to the Cancer Research Committee.

Yours very truly,
W. BLAIR BELL, Director.

THE STATISTICAL STUDY OF CANCER.

[We have received from Professor Blair Bell the following letter showing the position he had taken up in June, 1924, with regard to certain aspects of the statistics of cancer in relation to particular trades specially liable to lead poisoning. It seems appropriate to publish it here as a sequel to the memorandum of the Liverpool Research Committee.]

SIR,—The Medical Research Council has recently issued a report entitled "An investigation into the statistics of cancer in different trades and professions." Statistical findings in regard to matters of this kind rarely obtain unanimity even among statisticians themselves, and they are only generally accepted when they coincide with clinical and experimental experience. It is interesting to receive confirmation of this from statisticians concerned in their "Summary and Conclusions" to the report mentioned.

It follows, therefore, that when statisticians attempt to disprove practical observations they should be very sure of their figures in respect of all the conditions usually accepted by statisticians and ordinary folk as being necessary for accuracy. To quote me as admitting that the figures I have employed are too small for strict accuracy, and then to use the one set of the figures in which this is most definitely the case for the purpose of contradicting what I have merely said is *suggestive*, seems to me weak.

As my address to the North-Western Branch of the Society of Medical Officers of Health two years ago (*Public Health*, 1924, 217) is the object of attack, I feel that justice will be served if you will allow me the space to publish my remarks and figures on the subject, and also the remarks and figures from the report of the Medical Research Council. Unfortunately, the reports of the Medical Research Council and *Public Health* are not very generally read, and this makes me the more anxious to trespass on your valuable space, especially as the matter is of more than passing interest.

I think the unprejudiced reader will allow that I have been extremely cautious, and have weighed the matter in all its bearings, in spite of the fact that I make no pretence to being a statistician.

Extracts from Address by W. Blair Bell, published in "Public Health," 1924, xxxvii, 217.

"We have, therefore, been concerned in an attempt to discover whether persons poisoned with lead are less liable to malignant disease than the rest of the population; and, moreover, whether the decrease in the number of cases of lead poisoning as the result of legal enactments has led in particular occupations to an increase in the number of deaths from cancer.

"In the absence of precise records, it has been possible only to obtain evidence either of a personal character, or from statistics of doubtful value.

"In the first place I approached the Registrar-General, but he appears to be so little interested in the subject that he did not trouble to acknowledge, let alone reply to, my letter asking him if he could help me in the matter.

"In marked contrast with this has been the help I have received from those concerned in private enterprise—industrial and insurance—and I take this opportunity of acknowledging with gratitude their kindness and interest. Indeed, it was the following voluntary letter—slightly altered for publication by the sender, and with a few passages of a personal nature deleted—which stimulated my investigations in the matter, although I had previously made a few tentative inquiries from friends in the Midlands.

"Dear Sir,

"I have had, and still have, under my observation the chemical plumbers employed in the various works of the United Alkali Co. distributed over the country. This experience in managing chemical works has extended over the long period of more than 50 years, during which I have always taken a keen interest in the question of industrial diseases, such as plumbism associated with chemical manufacturing.

"From time to time I have read, with very great interest, the researches you are making, on the influence of salts of lead in the cure of cancer, and when I heard of your work it struck me that I had never, in my long experience, come across a case of cancer with the enormous number of chemical plumbers that have passed under my control. With this striking fact before

me I wrote to our managers in Glasgow, Newcastle, Bristol, Widnes, and Runcorn, to ascertain from them, from their own experience, and that of my old foremen and plumbers, whether their observations corroborated my own, and I enclose herewith the seven reports from these gentlemen, and one from Mr. Johnson of the Plumbers' Union, the contents of which will explain themselves, and from which you will see that my impressions have been amply confirmed by the fact that in no case have they found deaths from cancer amongst the chemical plumbers in their various works. This led me to address the communication to you, in order that I may direct your attention to these important facts, and which possibly may be of value to you in your researches, in which I take a very deep interest. This question, to my mind, divides itself into two parts:—1st: chemical plumbers, and 2nd: plumbers employed in house-building, shipbuilding, a make the following observations on the of these two classes of men, in respect likelihood of their absorbing lead, and thus enjoy immunity, or otherwise, from cancer.

"Chemical Plumbers.

"The chemical plumbers we employ are subject to the unfortunate disease of plumbism, but never to cancer, and I explain this fact in the following way.

"Our men are largely employed in building and repairing vitriol chambers, acid cisterns, and the like. For this purpose they burn the lead seams by the oxyhydrogen blow pipe, which gives a flame of intensely high temperature. As lead melts at the low temperature of 600° F. some certain portion of it is volatilized by this intensely hot flame, probably becomes immediately oxidized and breathed by the men in a fine state of division, producing symptoms of plumbism, but it has occurred to me that inhalation of this volatilized lead in minute quantities may have the important effect of explaining their immunity from cancer, and this view seems to be supported by the fact that none of us can find a genuine case of death from cancer amongst our chemical plumbers.

"House, etc., Plumbers.

"With regard to plumbers working in houses, ships, engineering, etc., the conditions of their work are entirely different. When water cisterns, etc., are lined with lead the seams are made by soldering with a bolt, the temperature being so low that little, or no, lead can be volatilized, as compared with that which rises from the intensely high temperature of the oxyhydrogen flame. In this manner we would expect that the house plumbers would not absorb lead to render them immune to cancer, but their death rate from that disease would probably be similar to that for ordinary workmen in other industries.

"All the information and figures that I have been able to get from the Plumbers' Union support this view.

"All these facts, therefore, to my mind, point to the important fact that the inhalation of volatilized lead by chemical plumbers not only explains the production of plumbism amongst them, but also the important fact that cancer amongst this class of men is unknown.

"I submit these data for your consideration from the medical point of view, in the belief that possibly they may throw some light upon the effect of lead compounds in preventing this terrible disease.

Yours truly,

(Signed) THOMAS W. STUART,
General Technical Manager, United
Alkali Co., Ltd.

"I do not think it necessary to append the letters received by Mr. Stuart from the various branches of the United Alkali Co. They are unanimous on the subject.

"The communication received from District Secretary of the United Operative Plumbers' and Domestic Engineers' Association is, however, worth quoting:

"I have been at the trade for 40 years and it will be easy for you to imagine that in such a long period a huge number of chemical plumbers have been known to me personally.

"Again, I have been an official in our association for 25 years and in such a position that all medical certificates pass through my hands, and in the whole of my experience I have never known a single case of cancer." [Italics by W. B. B.]

"I shall not comment on these remarkable statements, beyond saying that no criticism can destroy their value, for, even though a number of cases of cancer had been overlooked, the general truth of them would not be affected, since they concern 'a huge number' of men.

"With regard to the qualifications concerning house plumbers contained in Mr. Stuart's letter, in the statistics received from the Plumbers' Union no attempt is made to distinguish between the different types of plumbers, and, therefore, as Mr. Stuart says, no true relationship can be drawn between the mortality rate among this class of worker as a whole and the general population; but a matter of interest to be extracted from the figures supplied by the union is the rise in the cancer rate proportionately to a decrease in the number of deaths from plumbism.

"An analysis, from this point of view, of the figures given is shown in Table 2.

TABLE 2.—*Plumbism and Cancer.*
Percentage of all Deaths.

	1911-1914.		1920-1921.	
	Cancer.	Plumbism.	Cancer.	Plumbism.
Plumbers' Union	4.5	1.5	9.7	0.5
General male population, ages 25 to 65	6.0	—	10.0	—

"I well know that figures based on percentages of a small number of deaths from two variable diseases one of which is diluted may or may not approach statistical accuracy; but I am tempted to give them because they accord with the other evidence to be adduced.

"A similar, but also not entirely accurate, relation between the decrease in lead poisoning and the increase in the cancer mortality to which I have just referred, is shown in the mortality figures of England and Wales for the years 1900-1902 and 1910-1912, in relation to the three occupations in which lead poisoning is most prevalent (Table 3).

TABLE 3.—*Comparative Mortality Rate per 100,000 Population at Ages 25 to 65 years.*

	1920-1902.	1910-1912.	Percentage Increase or Decrease.
ALL MALES—			
Cancer	68	78	+15
Plumbism	1	1	0
FILE MAKERS—			
Cancer	57	78	+37
Plumbism	55	10	-82
LEAD MANUFACTURERS—			
Cancer	81	83	-1*
Plumbism	102	123	+21
PLUMBERS, PAINTERS, AND GLAZIERS—			
Cancer	73	87	+19
Plumbism	23	20	-13

* This is in reality a diminution of 16 per cent.; compare first group, showing normal increase.

"It will be observed that these figures, whatever value they may have, show that a decrease in the number of deaths from plumbism is accompanied by an increase in the mortality rate of cancer, and vice versa. The numbers are, however, too small for strict accuracy.

"Again, after the introduction of strict legislation in regard to the use of lead in the manufacture of pottery there is apparently an increase in the mortality rate of cancer among the workers concerned.

"From figures given by Hoffman we find that the standardized death rates from cancer among males over 15 years of age in 35 occupations showed an average rise of 15.6 per 100,000 of the population in the ten years between 1890-1892 and 1900-1902; but possibly owing to the legislation introduced in the middle of the decade—that is, in 1896—plumbism decreased, and the death rate from cancer among potters increased by 27.2 per 100,000 of the population concerned—11.6 per 100,000 above the general average. Had restrictions been introduced at the commencement of the period we might reasonably have expected a still greater increase in the mortality rate of cancer.

"It is only fair to state that in one or two other occupations the rise in the death rate from malignant diseases was greater, but I dare say that some cause could be found for the increases, if investigations were made. In striking contrast, however, was the decrease in the chimney-sweeps' cancer in the same period by -40.6 per 100,000. In this trade preventive measures had been directed against the cause of cancer.

"Further, Hoffman gives details of 2,452 deaths from cancer concerning which a considerable amount of information was forthcoming, and the probable predisposing causes were impartially recorded. In only three of these cases is lead poisoning mentioned along with other pathological conditions, and in only one is there anything to suggest that the patient may have been suffering from lead poisoning when attacked by cancer of the liver.

"Again I would insist that the value of these figures lies not in their infallible statistical accuracy, but in their suggestive harmony.

"I am afraid that my remarks have been more discursive than I had intended, and that the information submitted is suggestive rather than decisive. I hope, nevertheless, that what I have said may induce medical officers of health to look into the question of a possible relationship between lead poisoning and cancer, and to furnish statistics based on larger figures, properly standardized in the way indicated. By 'properly standardized' I do not mean only in regard to age and sex, but also to the possibility of cancer arising in a patient suffering with lead poisoning.

"I would, therefore, ask all public health authorities who can help in this matter to tabulate their mortality rates in regard to the male population between 25 and 65 years of age in the few occupations in which lead poisoning is possible, in such a way as to make it easy to discover whether there is any real evidence of comparative immunity from malignant disease in association with lead poisoning. Whether this will be found possible I do not know. A diluted mortality rate is unsatisfactory, and can demonstrate little more than I have already shown in the foregoing figures.

"The statements of Mr. Stuart are, however, of particular importance in that they deal with a class of worker who must inevitably absorb lead by inhalation. In such circumstances the whole of the men engaged can be considered poisoned, and the dilution effect would be infinitesimal. To take potters as a group would be useless, the dilution of the figures by at least 80 per cent. of those engaged, who never come in contact with lead, would falsify statistics to an extent that would render them useless.

"All statistics concerning the matter under discussion must, then, show:

- (a) Inevitability of lead poisoning.
- (b) Existence of lead poisoning.
- (c) The coexistence of one of these conditions with the onset of cancer."

Extract from Report of Medical Research Council, "An Investigation into the Statistics of Cancer in Different Trades and Professions," No. xcix, 1926.

"While the ingestion of metallic substances over a considerable period of time has been advanced by more than one observer as a predisposing cause of cancer, it may be mentioned that Blair Bell (1924), having found the administration of lead salts apparently of value in the treatment of malignant disease, has recently suggested that those who are exposed to lead poisoning or plumbism show a reduced mortality from it. From data supplied by the Plumbers' Union he concludes that, among plumbers, there has been a rise in the cancer rate which is proportionate to the decrease in the number of deaths from plumbism. He also compares the mortality statistics for plumbism and cancer in England and Wales in the two periods 1900-02 and 1910-12, and gives figures which appear to indicate, though he admits the numbers are too small for strict accuracy, that a decrease in the number of deaths from plumbism is accompanied by an increase in the mortality from cancer, and vice versa, in the occupational groups, file makers; lead manufacturers; and plumbers, painters and glaziers; in which occupations lead poisoning is most prevalent.

"With the view of ascertaining if the relationship suggested received confirmation from the data available, the following table has been compiled from Table V of the Supplement to the 75th Annual Report of the Registrar-General. In it are shown for the two triennial periods, 1900-02 and 1910-12, all the occupational groups with comparative mortality figures from lead poisoning above unity (1), the standard for occupied and retired males in England and Wales, in apposition with the comparative mortality figures for cancer in the corresponding groups.

Comparative Mortality Figures.

	1910-1912.		1900-1902.	
	Cancer.	Occupational Lead Poisoning.	Cancer.	Occupational Lead Poisoning.
Lead manufacturers	89	123	81	102
Potters	89	22	74	10
Plumbers, painters	87	22	73	23
File makers	78	10	57	56
Copper manufacturers	71	6	45	3
Gunsmiths	78	4	74	—
Printers	68	2	65	2
Glass-makers	81	2	71	8
Chemical manufacturers	71	—	85	3
Occupied and retired males	78	1	68	1
Clergy	45	—	48	—
Coal miners	61	—	53	—
Shipbuilders	64	—	55	—
Slaters, tilers	117	—	71	—
Furriers, skinner	82	—	115	—

"Out of eight groups with a comparative mortality figure for lead poisoning above the standard for England and Wales in 1900-02, only two are markedly low for cancer, while two are markedly high; in 1910-12 only one group, printers, is rather low, and only one, plumbers, is high. A few other groups with no cases of lead poisoning are also given in order to show that lower and higher cancer figures, with more pronounced variations in rise or fall, are to be found in other occupations than the "lead" occupations. These data do not reveal the connexion suggested between cancer and lead poisoning."

From this it is clear that the statisticians of the Medical Research Council have completely overlooked the matter of *proper standardization*, on which I laid much stress.

In conclusion, I may mention that I have recently received (December 22nd, 1925) a letter from Mr. Hoffman, the eminent American statistician, well known in regard to cancer mortality, who has been investigating lead poisoning in the United States; in this communication he writes:

"I am engaged in two extended investigations, one into cancer and one into chronic lead poisoning. With regard to both I am proceeding along much similar lines of investigation. I am dealing with original death certificates representing the entire mortality in the case of cancer for about twelve cities for the last five years, and for lead poisoning for the entire United States Registration Area, for the last eleven years. My lead poisoning investigation represents 1,592 deaths regarding which the standard death certificate reveals considerable interesting information. I am chiefly concerned with the occupational distribution and the collateral causes of death. As I have had occasion to say to you before, and in one of my publications, I have never yet found a case of chronic lead poisoning in which a tumour formation, whether malignant or benign, was mentioned as a collateral or contributory cause of death. Nor do I recall having ever seen a cancer death certificate, and I am dealing with more than 20,000 in my cancer investigation, in which lead poisoning was mentioned as a contributory cause of death in malignant diseases."

Surely the matter is worth proper investigation over many years on the lines I have suggested. Until this has been done no one can know whether what I have been careful to call "suggestive" is a positive fact or not.—I am, etc.,

Liverpool, Feb. 22nd.

W. BLAIR BELL.

TESTS FOR DRUNKENNESS.

DISCUSSION BY THE MARYLEBONE DIVISION.

A MEETING of the Marylebone Division of the British Medical Association was held on February 25th, when a discussion took place on tests for drunkenness. Lord DAWSON OF PENN presided.

Dr. JAMES MAUGHAN (Metropolitan Police Surgeon), in opening, confined his remarks to border-line cases and to the tests which had proved useful in deciding them. It was regrettable that no substitute had been found for the word "drunk." Susceptibility to alcohol varied within wide limits in different men, and even in the same man under different conditions. It seemed to be remarkably increased among men suffering from neurasthenia. Degrees of tolerance were important; in the toper an amount of alcohol which would quickly reduce a teetotaler to the condition of a log of wood was held up somewhere, to be released into the blood over an extended period. The signs presented by a man first at his arrest and then an hour afterwards might show marvellous differences. Dr. Maughan's own procedure at the police station was to elicit the particulars from the man, to encourage him to tell his story in his own way, noting meanwhile any incoherence in speech or disorder in behaviour, and any other suggestions of impaired self-control or disorientation. The tests applied depended largely upon the man's own leading. The mask-like face, with flushed cheeks, the quick soft pulse, the pupils, at times unequal, at times exhibiting hippus, and showing no reaction to a 2-c.p. light, difficulty in convergence of the eyeballs—these were all to be noted. On an alcoholic smell of the breath he passed no comment, and Romberg's test in many cases was not of much value; another test was intricate reading, such as the discovery from the time-table of the last train from Rugby to London on a Sunday, and again there was the pronunciation, which was the weakest of all tests—an unfair one if in his normal state a man had any defects of speech or

education. The writing test also might not be fair, unless in the case of a man such as a clerk accustomed to writing. Among persons in drink errors in respect to time were very frequent, and errors in respect to space fairly frequent. Many a time he had been solemnly assured by the drunken person that they were not in London but in Birmingham or somewhere else. The principle underlying the choice of tests should be scientific and rational. According to the physiologists alcohol that found its way into the cerebro-spinal fluid paralysed the synapses in the brain, with the result that the highest centres were cut off from one another, their directional mandate to the automatic mechanism was blocked, and their control over the lowest centres disappeared. In such circumstances one would expect to find gross inco-ordination of movements and uncontrolled release of elemental passions. If examination showed that, owing to alcohol, a man was suffering from a loss of the power of the higher centres to direct his automatic actions, he was drunk within the meaning of the law. Such a man, driving a car, for example, was likely to fail at the psychological moment when an emergency arose. It was disconcerting to find how many other causes besides alcohol might be cited to explain the results of the tests. For that reason it was desirable to use many tests in order to avoid injustice. Some reactions clearly indicated failure in sense reception or in the performance of skilled movements. Sometimes there was an isolation of the senses to such an extent that for the time being the man was a double entity, his higher powers even allowing him to look on, amused and interested, at the actions of his automatic self. On the other hand, some of the tests were purely reflex, and their only value was in the fact that paralysis of the reflexes and of the highest nervous centres happened to occur simultaneously in many cases. The most admirable control test would be to make a similar examination of the accused person when unquestionably sober.

Mr. VERNON GATTIE, a police magistrate, said that in the definition of drunkenness the dictionaries were not helpful. Taylor's *Medical Jurisprudence* defined "drunk" as follows:

"The" (not "a") "mental condition which arises in sentient beings as a result of taking alcoholic (usually) or etheral (less commonly) or other intoxicating (still more rarely) material. . . . A person is drunk within the meaning of the (judicial) proceedings if this mental condition has led him to behave in the manner which led to the proceedings."

It might be a good test to apply: Would he have acted in the same way if he had not had the liquor? Some of the tests appealed less to the layman than others. The pronunciation of "truly rural" did not seem to be of much value. Nor did the test in which it was noted whether the person swayed when standing with his heels together and his eyes closed. The police magistrate must rely on the doctor, who applied the tests which seemed to him proper. When there was a difference of opinion between two doctors the magistrate should give the accused, in that unsatisfactory phrase, "the benefit of the doubt," because the onus rested upon the prosecution to prove the charge, and with medical evidence to the contrary the charge was not proved. The doctor's evidence might be fortified by that of the police officer who saw the accused immediately after arrest, but the usual police "signs"—thickness of speech, unsteadiness of gait, and alcoholic breath, did not appeal much to the magistrate. A difficult point arose when the doctor said that at the time he examined the man, an hour or two after arrest, he was not drunk, but that in his opinion he had been drunk some while before. It must be difficult for a doctor to express such an opinion with any confidence, and the magistrate should hesitate before convicting. The corresponding case was that of the man who was drunk a couple of hours after the arrest, but quite possibly not at the time of the arrest. The arrest itself produced a shock to the nervous system, and might precipitate a worse condition than the man was in at the time the arrest, or perhaps the accident, occurred. Some men were highly excitable by nature, some had a curious pronunciation, with some the consumption of a very small amount of alcohol sufficed to give a smell to the breath, and some had an habitual incapacity to give any accurate account of their movements, and their ideas of time were normally vague. The magistrate must observe carefully the demeanour of the accused person during the proceedings, but his main reliance must be upon the doctor.

Dr. ANTHONY FELLING dealt with the subject from the neurological point of view. This was a condition, medically, of acute alcoholic poisoning which affected the nervous system, the alimentary tract, and the cardio-vascular and urinary systems. Alcohol affected the nervous system in the order of the evolutionary levels, the highest being the first to suffer. In the great majority of cases of drunkenness the question related to the slighter degrees of alcoholic poisoning, and in such cases it was the disturbances of the higher emotional mechanism which occurred. Here, therefore, the tests of the mental or emotional condition of the suspected person assumed a cardinal importance, but the difficulty of idiosyncrasy came in, hence the value of the testimony of the private medical attendant. Ample opportunity should be given to the accused to tell his own story. Abnormal garrulity on the one hand, or surly silence on the other, would go some way to corroborate suspicion, while a candid and fair story would clear away doubts engendered by peculiar conduct. On the next evolutionary level disturbance occurred in the power of performing finely co-ordinated movements. Not only should slurring of the speech and tremors of the hands be noted, but the manner in which the accused person received and interpreted the directions given. Romberg's sign was not a reliable test, many persons; even when in perfect health, exhibiting slight unsteadiness when standing with eyes closed: Assuming that the tests had established an *a priori* likelihood of drunkenness, the possibility had to be excluded of the disturbance being due to actual organic disease or even to the temporary effects of shock or profound excitement from other emotional causes. A careful examination of the muscular power of the limbs, of the functions of the cranial nerves, and of the reflexes should suffice in most cases to exclude organic disease, but so far as the tendon reflexes, the arm, the knee, and the ankle jerks were concerned, it was their absence or gross diminution which was important; a mere exaggeration of these reflexes was of little value in any case, and no value in the differential diagnosis of acute alcoholic poisoning. Judging by reports of cases, the reaction of the pupils to light appeared to have considerable importance attached to it, but alcohol had no constant effect on the pupils. The only characteristic condition was that to which attention was directed many years ago by Macewen, and later by Glaister—contracted pupils, dilated at once on any stimulus, but contracted again when the stimulus was withdrawn. Every case must be judged individually, and an opinion be arrived at only after careful consideration of all the facts and responses to tests. Recently tests had been suggested based on the chemical examination of the cerebro-spinal fluid or the urine. The examination of the former for alcohol might be dismissed as impracticable, and both tests were open to the valid objection that though they might show that alcohol had been consumed, and even approximately how much, they could not show whether any given person was drunk or not. One man might carry a bottle of whisky and not show it, and another might be drunk on two glasses of beer. Reliance must be placed on clinical tests, and standards of conduct and behaviour were the only criteria on which to depend in slight and difficult cases.

Dr. GRAHAM GRANT said that early in his career as a police surgeon he went to see a man who had been arrested for being drunk, and being enthusiastic at that time over certain tests, he declared him to be not drunk. The man was accordingly released, and, on going out of the police station, fell down the steps, and was brought back, so that he was compelled to certify him as drunk! One thing he had often found was that persons alleged to be drunk had an extraordinary capacity for sobering themselves under stress. They could make themselves apparently so sober that the inexperienced medical man was misled.

Dr. COURTENAY LORD said that he was particularly interested in this subject as secretary of the committee of the Association which had undertaken the bold task of considering the present tests for drunkenness with a view to some possible standardization. It was hoped to eliminate tests which experience had shown to have no value or doubtful value, and to establish others which could be used on all occasions by police surgeons, who, of course, could use their own discretion as to the application of supplementary tests as well. Such a result would relieve public anxiety, but even if no concrete proposals could be made a negative result would not be without value. As showing the difficulties with which the problem was hedged

about, he recalled one case from his own brief experience as a police surgeon—the case of a man arrested for riotous drunkenness, whose conversation was perfectly sensible, and not until he began to quote Shakespeare did the speaker really think him drunk. But next day that man admitted to him that he had no recollection at all of anything which occurred from the time he left the scene of his jollification to the hour when he woke up in his cell the next morning.

Lord DAWSON remarked that the general opinion about drunkenness had changed. This country, under conditions of freedom, was steadily becoming more sober, as everybody who worked among the industrial classes would admit. Drunkenness to-day, therefore, was judged from a stricter standard than formerly. The activities of modern life also demanded from the community a much higher degree of sobriety. To drive a motor car called for an acute condition of mind, a quick judgement such as our forefathers were rarely called upon to exercise. An alcoholic state which, fifty years ago, might have called for no interference or censure must now receive attention because, under the conditions of modern life, it made the individual capable of antisocial conduct previously unknown. It followed that the tests for drunkenness must be applied almost exclusively to the higher centres. The police surgeon, like the practitioner in any other field of medicine, had a far more difficult task to-day than was the case years ago; if the means available for examination and diagnosis had improved, concurrently had the complexity of the problem increased. He added an expression of the hope that the term "neurasthenia" would be used as little as possible. In the war it was made to mean anything or nothing, and sometimes was regarded as identical with malingering and humbug. It would be a poor result to get out of the difficulties about "drunkenness" by taking refuge in "neurasthenia."

Dr. P. B. SPURGIN (Metropolitan Police Surgeon) agreed that the words "drunk" and "drunkenness" were clumsy, unscientific, and unsuitable, but they met the views of the public more or less. He would suggest as a definition "suffering from the effects of alcoholic toxæmia." The public had been made uncomfortable by the press with regard to drunkenness, especially in motor-car cases. The public did not know of the large proportion of cases which never reached the police court and publicity—namely, those in which the divisional surgeon was able to certify as not drunk a person who had been brought in by the police. He believed that there had never been a case taken into the court in which there was not reliable and consistent evidence of a state of drunkenness. In cross-examination he had admitted that the result of one test after another might be explained in some other way, but when the cross-examining counsel exclaimed in triumph at the end of the recital of the tests that there was therefore no evidence of drunkenness he was discomfited on it being pointed out to him that although the result in each test might be otherwise explainable, the result of the whole series of tests together corresponded to nothing except alcoholism, and the magistrate generally agreed.

Mr. BISHOP HARMAN said that Dr. Maughan had appeared to think that the test of failure of convergence was a very good one, but in fact it was a very common disability. It occurred among a large number of his own patients, of whom he would be very much surprised to learn that they were suffering from alcoholism in any degree whatever.

A VISITOR, who had been a naval surgeon, said that in the navy it was not the surgeon who stated whether or not a man was drunk, but the officer of the watch, who applied the simple test of whether the man was or was not fit for duty. Questions of conduct could be judged to a considerable extent by any reasonable person.

Dr. D. ROXBURGH, who had taken the chair, Lord Dawson having to leave the meeting, remarked that unsteadiness of gait should not be regarded as a sign of drunkenness, in view of the number of people who suffered from giddiness, especially after an influenza attack.

Dr. MAUGHAN, in reply, agreed that the nature and variety of cases of drunkenness had altered during the last thirty or forty years. In the old days the "drunks" used to be far more pugnacious, and frequently had to be held down. He recalled, in closing, a story of Dr. Mercier. When someone said that there was an analogy between alcoholism and insanity Mercier laughed, and, asked why he did so, explained, "It is absurd to say they are analogous, they are identical."

PRINCIPLES OF TREATMENT IN DISEASES OF THE NERVOUS SYSTEM.

SECOND LETTSOMIAN LECTURE.*

IN his second Lettsomian lecture, delivered at the Medical Society of London on February 24th, Dr. E. FARQUHAR BUZZARD began by speaking of the indications for surgical intervention in tumours of the brain. His respect for brain surgery, he said, had been growing for many years. It was impossible for anyone who had not seen and followed a large number of cases to appreciate the value of surgical intervention in relation to brain tumours. The results of such intervention were far more satisfactory now than they were twenty years ago, and the credit for this should be allowed, not solely to advance in surgical skill and judgement, but also to the fact that diagnosis was, on the whole, made earlier and more accurately.

Intracranial Surgery.

The lecturer said that intracranial exploration was a field of surgery which was rich in surprises. When everything seemed to point to the presence of an infiltrating glioma, with its attendant bad prognosis, the result of the exploration might be to find an endothelioma or chronic abscess, capable of complete removal. The most promising group of cases of intracranial tumour from the point of view of permanent relief afforded by operation was that in which headache, vomiting, and optic neuritis were often conspicuous by their absence. In spite of the general teaching that these must be regarded as cardinal symptoms of intracranial tumour, cases in which these were not present provided perhaps the majority of examples of successful treatment. This was not merely a question of early diagnosis—although it meant much to the surgeon that his services should be called upon before intracranial tension was so much raised—but it was due to the fact that slow-growing endotheliomata might reach a very large size without provoking the cardinal symptoms, and that they could often be entirely removed with little fear of any recurrence.

The localization of intracranial lesions was not to be regarded as a difficult task compared with that of determining their nature. If, on the other hand, the tumour was so placed that its removal was out of the question there was no need to ascertain its nature by exploration, although a decompression might be indicated for the purpose of relieving suffering. This operation should be avoided, however, if relief could be afforded by other measures.

Epilepsy.

The last quarter of a century (Dr. Buzzard continued), though not devoid of praiseworthy efforts, had seen little light thrown on the pathogenesis of epilepsy, and had supplied no substantial reasons for altering what might be termed its traditional treatment. Confining his remarks to the principles governing the treatment of epilepsy in its earliest stages, he said that he accepted the view that epilepsy was a manifestation of instability on the part of some important nervous mechanism closely related to, if not identical with, the vasomotor system. Epileptic attacks he regarded as only the outward and visible signs of some permanent underlying nervous state which was inherent in a certain proportion of the population. While it was true that psychological investigations had seemed to show that the minds of most epileptics approximated to a certain type, workers in this field of research would not suggest that that type of mind was confined to epileptics, nor did they attempt to explain why only a proportion of persons possessing it were subject to fits. The early diagnosis of epileptic instability, before any of its manifestations had appeared on the scene, was an ideal which in the present state of knowledge seemed almost out of reach, but the next best thing would be a general recognition of its most trivial "embryonic" signs, such as the so-called regional jerks, which preceded other epileptic phenomena by many months and sometimes years, and a certain momentary interruption in the continuity of a patient's mental processes, associated perhaps with some local sensory disturbances or with what the patient might call a "wave of unreality."

The lecturer proceeded to lay down the principle that any manifestation of epilepsy in childhood should ensure treatment being persevered with until adult life, however successful the treatment might have been in preventing any repetition of the first sign. Even then cessation of treatment should be carried out gradually and with caution. In treatment each case must be studied as a separate problem. Measures should be taken to avoid what appeared to be the exciting cause, such as emotional disturbances, fatigue, and dietary indiscretions, but the child's life should be made as little different from that of his fellows as possible. Septic tonsils, adenoids, errors of refraction, and vulvitis, no doubt, might play a part as exciting causes, but their correction did not relieve the doctor of his responsibility for dealing with the underlying instability, without which no manifestation of epilepsy would have made its appearance. As to medicinal measures the bromides had been convicted, through no fault of their own, of many crimes of which they were not really guilty. Given irregularly or for too short a time, they were blamed for lack of success; given in too large or too frequent doses, they were held responsible for inevitable toxic states; given in appropriate doses without success—a result which might often ensue, especially when their use had been too long delayed—the depression really attendant on their failure to cure was laid at their door. Bromides should be prescribed, in his opinion, as soon as any manifestation of epilepsy made its appearance, the dose should be the minimum required for its purpose, and the number of doses in twenty-four hours should be as small as possible, and timed in accordance with any special features of the case under consideration. The administration must be regular and continued for an indefinite time according to age and other circumstances, and a small quantity of arsenic, two or three minims of Fowler's solution, should always be given with the bromide. Luminal had proved useful sometimes alone, but more often with bromide. Belladonna, borax, and digitalis might be added to bromide sometimes with advantage.

Syphilis of the Nervous System and Disseminated Sclerosis.

Dr. Buzzard said that, with certain exceptions, the patients who presented themselves with tabes dorsalis, general paralysis of the insane, cerebral syphilis, syphilitic myelitis, and so forth had been sacrificed to the time-honoured but groundless tradition that a medical man possessed the knowledge which justified him in telling a patient that he had been cured of his syphilis. It was true that large numbers of patients suffering from syphilis were cured, but medical men had no means of deciding in any particular case whether or not a cure had been effected. The public had always asked for cures, and in deference to their wishes the medical profession had weakly claimed the power to cure. With regard to what were known as the parenchymatous forms of syphilis of the nervous system, general paralysis and tabes dorsalis, the results of anti-syphilitic treatment were less constant in their encouragement. The first disease had still to be considered as incurable. Tabes in its early stages had at any rate been checked, and held in check, by repeated courses of mercury and of the arsenical compounds or by a judicious combination of these metals. The principles governing the treatment of syphilis of the nervous system did not really differ from those governing the treatment of syphilis of other organs, but in view of the special nature of the nervous tissues the importance of early diagnosis could not be too strongly urged.

With regard to disseminated sclerosis, he held the view that if the principles governing the treatment of syphilis were applied, in spite of ignorance as to the causal agent in sclerosis, the results were often too striking to be disregarded or to be attributed entirely to chance. Arsenic and mercury were employed more and more frequently in the treatment of this disease, but success, as in the case of syphilis, was mainly dependent on early diagnosis and on the indefinitely continued administration of these two metals. He did not believe arsenic had specific powers in combating disseminated sclerosis, but a long experience of its effect in such cases led him to think that if used early and perseveringly it was the best weapon available.

* A report of Dr. Buzzard's first lecture appeared in the JOURNAL of February 20th (p. 333). His third and concluding lecture is to be delivered on March 12th.

British Medical Journal.

SATURDAY, MARCH 6TH, 1926.

STATISTICAL STUDIES ON CANCER OF THE BREAST.

IN a previous report issued by the Ministry of Health's Departmental Committee on Cancer, to which we drew attention in our issue of October 4th, 1924 (p. 628), Dr. Janet E. Lane-Claypon presented valuable statistical information on cancer of the breast in relation to its surgical treatment. Perhaps even more valuable are the results which she has now published, dealing mainly with the associated antecedent conditions, local and general, in mammary cancer.¹ We are still in complete ignorance regarding the direct causative factors of breast cancer, nor, in spite of countless articles and monographs on the subject, is there general agreement as to the relative importance, or even existence, of contributory or predisposing causes. It is true that the Japanese experimenters Yamagiwa and Ishikawa, who first produced cancer of the skin in rabbits by repeated applications of coal tar, claimed to have induced carcinoma of the mammary gland in these animals by repeated local injections of tar, though their claim does not seem to be admitted by competent judges; but no one has succeeded in reproducing the disease experimentally under conditions that are likely to obtain in the case of the human cancer, possibly because no one knows what these conditions are. Properly conducted investigations into preceding or attendant conditions over a sufficiently large number of cases, non-cancerous as well as cancerous, and with reliable statistical methods, may prove useful in eliciting facts that will help in the elucidation of the etiology, or at least in dispelling prevalent misconceptions. Dr. Lane-Claypon has analysed the previous histories of some 500 women suffering from cancer of the breast in comparison with those of a like number of women over the age of 45 who were free of cancer in any part of the body. Care was taken to make the two groups as strictly comparable as possible. Though nothing that may be called new or startling emerged from these comparisons, the study is of considerable importance in providing us with exact figures instead of impressions, and in eliminating personal bias.

Dealing first of all with such phases of normal sexual activity as could be measured statistically, it was found that only very small, and probably negligible, differences could be detected in the menstrual histories of the two classes, but definite divergences could be established in respect of fertility. The incidence of mammary cancer is higher in the unmarried than in married women, as is generally known, but these studies further reveal that the greater the fertility the lower the liability to cancer of the breast. The figures are most critically considered by Dr. Major Greenwood, who contributes a special chapter on the point, and he shows that after making all allowances for circumstances such as might vitiate the comparisons the divergence is very striking, the difference being of the order of 22 per cent. This is all the

more remarkable as a similar comparison of relative fertility does not exhibit this difference in the case of cancer of the uterus. Lactation for any period from six months up to two years is without relation to any subsequent development of cancer; on the other hand, the absence of lactation or its prolongation beyond two years would appear to have a detrimental effect on the breast in this connexion, but sufficiently large numbers were not available to allow emphasis to be put on the point. Unilateral lactation could not be shown to exercise any deleterious influence in causing cancer of the breast exclusively used.

It is commonly assumed, probably not without justification, that cancer is the terminal phase of some other lesions less grave in themselves, and if we could establish a constant, or even a frequent, preceding lesion, preventive measures might be adopted with success. We turn with interest, therefore, to the section of the report dealing with previous troubles of the mammary gland. These have been divided into three groups—namely, those associated with lactation, developmental or functional errors, and injuries of various kinds. Such troubles as suppurative puerperal mastitis and cracked nipples seem to play no part in predisposing the breast to cancer; on the other hand, non-suppurative or transient mastitis associated with lactation does exert a baneful influence which is far from negligible in Dr. Lane-Claypon's opinion; to a less extent this applies also to structural and functional abnormalities; but where the great divergence arises between the two groups is in respect of antecedent injuries to the organ. That there is a close association between injury and the subsequent development of cancer the figures amply demonstrate, but it may still be doubted whether the statistical method is conclusive on such a point as this. It is probable that the part played by injury is exaggerated, for a person who develops cancer of an organ so liable to injury as the breast is much more likely to dig out from "the subconscious memory" instances of injury than one who is not suffering from cancer and has no stimulus to recall to recollection such occurrences. It is significant that the average time elapsing between the recalled injury and the development of cancer is short in comparison with the interval between other breast troubles and the appearance of the cancer. The figures do not disclose any important hereditary tendency to cancer of the breast, nor do they argue against such a possibility, for the nature of the material does not admit of precise deductions.

The symptoms of which the patients complained are tabulated and described in detail. The point of most importance which emerges is the high proportion of cases associated with pain at one stage or another, sometimes before any lump was felt. It is suggested that where pain in the breast is complained of the patient should be kept under observation, and there is reason to believe that the pain which is felt early in the disease is of a more intermittent character than that which supervenes later. Some interesting particulars are given regarding the stage of the disease when the patients present themselves for examination. About 80 per cent. of all the women applied for hospital advice without consulting a private practitioner; and too often those who sought private advice were advised to delay and report subsequent progress. The mean interval elapsing between observing the growth and applying for treatment was about ten months for those who survived the operation for less than three years, and not more than 15 per cent. of the patients presented themselves at a stage of the disease

¹ A Further Report on Cancer of the Breast, with Special Reference to its Associated Antecedent Conditions. By Janet E. Lane-Claypon, M.D., D.Sc. Lond. Ministry of Health Reports on Public Health and Medical Subjects. No. 32. 1926. London: H.M. Stationery Office. 3s. net.

when any effective remedial measures could be taken. Sir George Newman, commenting on this in the preface to the report, emphasizes the fact that "a mass of disease and suffering is still needlessly continuing which we already have ample means at our disposal to prevent." The spread of knowledge by intelligent propaganda ought to save many lives.

The vexed question of the relationship of "chronic mastitis" to cancer of the breast is considered at length, and this part of the report will repay study by those who believe in as well as by those who doubt the relationship. While recognizing that the data at present available are insufficient to afford a basis for a theory for the development of cancer of the breast, the author sums up her views as follows: "The continually recurring changes of the menstrual cycle have an important bearing upon the whole process, since there is evidence of an inverse relationship between fertility and cancer of the breast. Probably at some period, and for causes at present unknown, one of which, however, may well be injury, one part of the breast does not follow the ordinary cycle of the rest of the tissue. This departure from normality may gradually recede, or may become accentuated. . . . When accentuated, a condition of hyperplasia may result from the cumulative effect of a constantly recurring stimulus. The evidence dealing with the passage of hyperplasia to a condition of malignancy, while not absolutely positive, is yet of such a nature as to leave little room for doubt that it does occur."

UNQUALIFIED MEDICAL PRACTICE.

THE discussion on unqualified practice and the attitude of the medical profession and the authorities of the medical profession thereto, to which we devoted some attention a fortnight ago, has been advanced by the meeting of Peers and members of the House of Commons, of which a report will be found at page 450. Lord Dawson's address at that meeting was wise, temperate, and conciliatory, and its effect should be to dissipate still further the fog in which this matter has become enveloped. As Lord Dawson said, the subject has been "overlaid with a certain diffuseness and bitterness of spirit." As long as these persist some people will not see clearly even in a serene atmosphere; and though such an atmosphere is unquestionably a good thing, one can, in fact, become too placable. Mischievous error has to be withstood, not propitiated; and unjust charges may well be denied emphatically and without qualification or apology. Pervading all the activities of certain journalists and the speeches of certain members of Parliament on this matter, there seems to be the accusation or assumption that professional rules or customs in regard to relations with unqualified practitioners, and to public pronouncements on medical matters, have as their sole or primary object the obtaining of some advantage for registered practitioners. It is by no means easy to see how such advantage would accrue, and no attempt is made to show it. The very rules and customs themselves are usually misstated or misunderstood; but as the debate proceeds there is less and less excuse for these misstatements and misunderstandings, and it should be clear that not only, as Lord Dawson said, does the profession accept the good of the public as the overriding principle, but that it is exactly this public good which professional rules and customs are designed to promote and do in fact subserve.

Obscurity in the discussion would be avoided, not

only by accuracy as to facts and freedom from bitterness, but by constant awareness of certain distinctions of fundamental importance which ought to be, but apparently are not, obvious. One of these is the distinction between scientific knowledge and manual dexterity, between a theory of the causation of disease in general and the practical treatment of certain limited classes of case. A "bonesetter" used to mean a person who professed to have a special knack in dealing with injuries or displacements of the bones or joints. The "osteopath" of to-day is a person who treats all forms of disease by manipulation of the bones or joints on the professed theory that all disease is caused by misplacements of bone and consequent pressure on nerves and blood vessels. His hated rival the "chiropractor" is said to restrict manipulations to the spinal column. Now these theories of disease are, of course, what Lord Dawson called them, "sheer buffoonery," and treatment based upon them not only may be, but demonstrably very often is, dangerous; whereas manipulative skill within its proper range, and based upon accurate diagnosis, may be not merely useful but even essential for success in treatment. But when it is argued that "osteopathy" or "manipulative surgery" should receive a certain official status or recognition, we are bound to ask what the words exactly connote. Impossible claims can then be rejected and more restricted and logical requirements met.

The present claim that there should be a register of "qualified" osteopaths, on an equality with and possessing essentially the same rights as registered medical practitioners, ignores a further distinction—that between the requirement of at least a minimum amount of knowledge and training tested at every stage, and the imposition of a limitation upon opinion or practice. The former does not connote the latter to any degree whatever. Although in this country unqualified practice (except in dentistry and midwifery) is not forbidden by law, it is by general consent inadvisable for the State to recognize such practice except upon a basis of knowledge and training, and such State recognition cannot be based upon essentially different minima. Is it argued that there should be separate curriculums, separate colleges, separate tests, for those students who are eventually going to act upon the assumption that all disease is due to pyorrhoea alveolaris, or to the presence of a large intestine, or to bony displacements, or to "subluxation of the spine," or to anything they please? In the medical profession, after evidence of the possession of the required fundamental knowledge, a practitioner is at liberty to hold any opinions he likes, to give expression to them by proper means, and to base his practice upon them. The only restrictions on him are his own conscience, the recognized limits of professional discussion, and the judgement of the public. The Minister of Health was no doubt right when he said that there is nothing to prevent osteopaths setting up their own colleges and giving their own diplomas, but, as has happened in America, the curriculum of any such colleges would have to approach the normal medical curriculum before any guarantee could be given to the public by means of State recognition and registration.

A third distinction which it may be worth while to mention at the present time is that between legitimate public health propaganda and public pronouncements by registered medical practitioners for the purpose of personal advertisement or gain. Under the heading "Having it both ways" an important newspaper has

assumed a contradiction between the warning issued by the General Medical Council against the latter practice, and the encouragement given by the Ministry of Health to the former. There is, we need hardly say, no such contradiction; still less is there any ostensible or implied restriction upon the particular opinions which may be expressed in the course of health propaganda work. There are admittedly cases in which it is difficult to draw the line as to what is legitimate and seemly, especially as motive may be the essence of the case; but effective health propaganda is one of the duties of the profession. The Representative Body of the British Medical Association laid down some excellent considerations for guidance when it adopted last year the Council's report on indirect methods of advertising.¹

REPORT OF THE ROYAL COMMISSION ON NATIONAL HEALTH INSURANCE.

THE eagerly awaited report of the Royal Commission, appointed in July, 1924, to inquire into the scheme of National Health Insurance, has been issued this week. The Commission, it will be recalled, was set up in accordance with a promise made by Sir William Joynson-Hicks, when Minister of Health, during the negotiations in the previous autumn with the Insurance Acts Committee of the British Medical Association as to the terms of service of insurance practitioners. Its reference, as settled by his successor, Mr. John Wheatley, was shown beforehand in draft to the Insurance Acts Committee, and was accepted by that Committee and by the medical profession generally as allowing of the wide inquiry expected. The report is a large and comprehensive document of more than 400 pages. By far the greater part consists of a Majority Report signed by the chairman (Lord Lawrence of Kingsgate), Sir John Anderson, Sir Humphry Rolleston, Sir Alfred Watson, Sir Arthur Worley, Sir Andrew Duncan, Mr. Digby Besant, Professor Alexander Gray, and Mr. William Jones. A detailed summary of the conclusions at which the majority have arrived, and of the recommendations they submit, is reproduced in full in the SUPPLEMENT this week, together with a summary of the conclusions and recommendations put forward in a Minority Report signed by Mr. James Cook, Mr. John Evans, Mrs. Harrison Bell, and Miss Tuckwell.

It will be seen that all the members of the Commission concur in the opinion that National Health Insurance has established its position as a permanent feature of the social system of this country, and should be continued on its present compulsory and contributory basis, subject to various changes indicated in the two reports. The Commissioners appear to be at one also in concluding that medical benefit has been a valued and successful element in the scheme, but that while this has inevitably been hitherto confined to a general practitioner service, such limitation has detracted from the value of the benefit, and its removal is desirable. Among the many points put forward in the main body of the report we may note especially the recommendation that Insurance Committees should be abolished and their duties transferred to committees of the appropriate local authorities; also that, as and when funds are available by partial pooling of the surpluses of Approved Societies, there should be an extension of statutory

benefits for insured persons, the first of which ought to be a widening of the scope of medical benefit to include expert medical advice and treatment and laboratory services. In any scheme for extending the scope of medical benefit the Commissioners hold that provision should be made for the closest co-operation between general practitioners and specialists, and that any practitioner possessing the requisite qualifications should be entitled to take part in the work. The findings of the Minority Report include the opinion that it is undesirable to retain Approved Societies any longer as the agencies for the distribution of cash benefits to insured persons, and that local authorities should take their place. A reservation (which should rather be called an addendum) by two signatories of the Majority Report—Sir Andrew Duncan and Professor Gray—discusses the lack of co-ordination in respect of our social services, the relation between an insurance scheme and the prevention of sickness, the relation between expenditure on health and national finance, and the burden of the tax on industry.

The summaries published in the SUPPLEMENT will enable our readers to grasp the main features of this important document. Comment on a report of such length and complexity must, of course, be deferred to a later issue.

PYELOGRAPHY.

PYELOGRAPHY has now found a definite place in clinical medicine, but, as Mr. R. J. Willan reminds us in his lecture on the subject published at page 409 this week, considerable difficulty still exists in the interpretation of pyelograms. The normal renal pelvis is subject to a great range of variations, and what at one time were considered to be pathological abnormalities are now regarded as varieties of the healthy kidney. Nevertheless, in spite of these difficulties, great progress has been made in the art of pyelography. By it may be diagnosed lesions which would otherwise escape detection. Indeed, it may be said that the only method of detecting the early stages of such a condition as hydronephrosis is by the use of pyelography, and, as an early diagnosis of this condition is essential if the kidney is to be saved, an enormous advantage is thereby conferred. Progress has also been made in technique since Voelcker and von Lichtenberg introduced a 5 per cent. solution of collargol as the best medium for distending the pelvis. At the present time solutions of sodium bromide and of potassium iodide are the most popular. The use of a crystalline salt is clearly preferable to that of a colloid. It has been shown experimentally that a certain quantity of the fluid with which the pelvis is distended finds its way by imbibition along the tubules of the kidney. This is liable to cause nephritis, as shown by the appearance of casts, pus cells, and renal epithelium in the urine. If an easily soluble substance like sodium bromide be employed, it becomes rapidly diluted on entering the renal tubules, and such irritating properties as it may possess are thereby diminished. It is seldom that one sees nowadays a reaction after pyelography provided that catheterization has been carried out with an aseptic technique, and that the pelvis is distended with the utmost carefulness and gentleness. The improvement in the construction of catheterizing cystoscopes that has taken place in the last twenty years has added still further to the ease with which a pyelogram is made, and it should now be within the province of any surgeon possessing reasonable cystoscopic skill to use this method of diagnosis in all doubtful cases. Mr. Willan in his interesting article gives some indication of the type of case on which the pyelogram may throw light.

THE "BRITISH PHARMACOPOEIA."

A CONFERENCE took place at the offices of the General Medical Council on February 23rd between the members of the Pharmacopoeia Committee of the Council and representatives of certain medical, scientific, and pharmaceutical societies. The Pharmacopoeia Committee consists of Sir Donald MacAlister, Bt. (chairman), Sir Robert Bolam, Sir Humphry Rolleston, Bt., Sir Nestor Tirard, Sir Holburt Waring, Professor R. B. Wild, Dr. J. A. Adams, Professor Ashley W. Mackintosh, Sir Norman Walker, Dr. Leonard Kidd, Dr. Edward Magennis, Sir John Moore, and Dr. Philip Hamill (secretary). The representatives who met the Committee were: Dr. J. Smith Whitaker and Dr. E. W. Adams (Ministry of Health), Dr. H. H. Dale and Sir David Prain (Royal Society), Sir W. Hale-White and Professor A. J. Clark (Royal Society of Medicine), Dr. T. R. Elliott and Sir Walter Fletcher (Medical Research Council), Mr. E. Lewis Lilley and Dr. John W. Bone (British Medical Association), Mr. P. F. Rowsell and Mr. Edmond White (Pharmaceutical Society), the late Professor A. R. Cushny and Professor W. E. Dixon (Physiological Society), Professor F. G. Donnan (Chemical Society), Dr. A. B. Rendle and Lieut.-Colonel A. T. Gago (Linnean Society), Mr. H. Todd and Mr. W. J. Hardy (Northern Ireland Pharmaceutical Society), Mr. G. A. MacLean Lee and Mr. J. Smith (Southern Ireland Pharmaceutical Society), and Mr. A. Chaston Chapman and Mr. E. Hinks (Society of Public Analysts). The President outlined the history of the past issues of the *British Pharmacopoeia* and the present position as regards its revision. He mentioned that the Dominion of Canada had made a suggestion which might result in arrangements being made for the fuller consideration of specially Canadian requirements, and said it was probable that if anything was done on these lines similar arrangements would have to be made for ascertaining the special requirements of other parts of the Overseas Dominions, such as India, Australia, and South Africa. The delegates from the societies brought forward certain proposals concerning the method of revision, and many suggestions on the subject were offered. At the conclusion of the conference the President stated that these proposals and suggestions would be carefully considered by the Pharmacopoeia Committee at a meeting about the middle of March, after which he would ask the delegates to meet the Pharmacopoeia Committee again. On the motion of Sir William Hale-White a hearty vote of thanks was accorded to the Council for its action in inviting the conference.

EARLY WORKERS IN PUBLIC HEALTH.

SIR GEORGE NEWMAN'S Oration¹ to the Hunterian Society exhibits that breadth of view and quick appreciation of the essentials of his subject which experience of his writings leads the reader to expect. The great bulk of the medical profession are still occupied with the art of healing the sick, but a continually increasing minority are concerned primarily with the prevention of disease. There is much unavoidable, and indeed valuable, overlapping between the two, and the General Medical Council has decreed that every student, however he may develop and specialize later on, shall, to begin with, be educated in both aspects of medicine. The Chief Medical Officer's deliverances are always in readable and vigorous language, and in this oration he shows how in John Hunter's time and throughout the eighteenth century, before any specialism in disease prevention had formally developed, some great practitioners like Edward Jenner, Richard Mead, Lind, Haygarth, Blane, Huxham, and others were laying the

foundations of the science which seeks to protect humanity against invisible dangers on every side. Like Sir John Simon, who was the first to occupy the post of chief medical health adviser to the Government, Sir George Newman has an extensive knowledge of the literature of the subject, and in this pamphlet of fewer than fifty pages he gives his readers the benefit of his study of the discoveries of the Hunterian period. The oration, indeed, is a masterly survey of the pioneer work of a century of scientific development closely bearing on the welfare of the civilized world. In his easy-chair over an evening pipe when his day's work is finished a busy doctor may, with the oration in his hands, spend a pleasant hour communing with the great men of the past, thinking of the astonishing differences between then and now, and speculating as to the possible further revelations of Nature's secrets which may lie open to some successor of his at the end of the twentieth century, of which only one-fourth is already behind us.

THERAPEUTIC USES OF KAOLIN.

THE use of china clay or kaolin for the manufacture of porcelain has long flourished in the Orient, and since the eighteenth century centres at Limoges in France, and in Devon and Cornwall in this country, have supplied many thousands of tons annually. Its use in medicine as an excipient for certain pills, as a dusting powder for ulcerated surfaces, and as a basis of a form of poultice, has also been known for a long time. Of recent years the use of kaolin has been extended, however, and it is coming into favour for the treatment of certain intestinal infections. A discussion of its action in this respect formed the basis of a recent thesis¹ by Dr. L. H. Braadfladt, who had an opportunity for an extensive trial of its properties during the cholera epidemic in China which began in 1919. A hundred consecutive cases of cholera were selected, and divided into two groups according to their severity. Of these, 15 in the severely ill group and 20 in the moderately ill group received kaolin. It was given by the mouth in a heavy suspension consisting of 800 grams in a litre of water. If vomiting was a prominent symptom 3 ounces of this suspension was given every half-hour. After the vomiting and diarrhoea had abated slightly, usually at the end of six to eight hours, the dose of kaolin was continued every hour and then every two hours. It was not found necessary to give it for more than twelve to fifteen hours in most cases. Of the 35 patients who received kaolin only 1 died, and she was unconscious on admission and had complete suppression of urine. Of the total of 100 patients, 41 received hypertonic salt solution only with 9 deaths, 24 received salt solution and kaolin with 7 deaths, while 35 received kaolin alone with 1 death. In the two clinical groups the mortality rate was 22 per cent. in the severely ill and 6 per cent. in the moderately ill, so the therapeutic use of kaolin in cholera appears to be justified. Certain experimental work gives a clue to the way in which kaolin acts. When mixed with cultures of bacteria in fluid media, incubated at body temperature, and kept in motion, kaolin carries down with it as a precipitate large numbers of the organisms. If 25 mg. of the powder be mixed with one minimum lethal dose of diphtheria toxin this will fail to kill a guinea-pig on injection. Toxic filtrates of cultures of the cholera vibrio standardized to kill rabbits in 2 c.cm. doses by intravenous injection produce no toxic effects when previously shaken up with kaolin. Dr. Braadfladt concludes, therefore, that kaolin does not act as an antiseptic, but carries down with it large numbers of the bacteria in the intestine, while with regard to toxins it seems to render them harmless by a process of adsorption. Experiments on normal individuals indicate that after kaolin has been

¹ *The Private Practitioner as Pioneer in Preventive Medicine. Being the Annual Oration of the Hunterian Society, 1926. By Sir George Newman, M.D., D.C.L. Oxford University Press. London: Humphrey*

taken by the mouth *B. welchii*, for example, disappears almost completely from the faeces. It does not upset digestion, and it tends to reduce intestinal fermentation as evidenced by flatulence. It has been used in the treatment of bacillary dysentery, chronic ulcerative colitis, and acute enteritis with success, and it might possibly be beneficial in food poisoning by members of the salmonella group if given early enough. Dr. Braadfladt's results, with their experimental basis, suggest that the use of kaolin in intestinal infections deserves an extended trial.

IMAGINATION AS A METHOD OF TREATMENT.

At the social evening of the Royal Society of Medicine on March 1st an address was given by Dr. Gustave Monod of Paris and Vichy on "Imagination as a method of treatment." Sir StClair Thomson presided over a distinguished company which filled the Barnes Hall to overflowing. Dr. Monod first spoke of Cagliostro (Joseph Balsamo), the charlatan of the eighteenth century, who, after studying medicine and chemistry, wandered in many countries posing as a prophet and magician. A certain reputation attached to him, at Strasbourg and in Switzerland, as one who brought about rapid recoveries from diseases diagnosed as mortal. Mass suggestion, as M. Coué had discovered for himself in our own day, was an important factor in healing by the imagination. Cagliostro's panacea was spirits of wine distilled on sulphate of antimony, and he had a famous mirror for conveying suggestions to his patients. His powerful personality, his consummate stage management, his weird polyglot verbiage, as incomprehensible to his auditors as to himself, constituted his technique, and it was not disputed that many of his cures were authentic. The second example was David Gruby, a regular physician of Paris in the nineteenth century. The technique of this famous practitioner was perfect simplicity; he drove his commonplace devices into the subconscious mind of his patient with unerring skill. His prescriptions were legendary in Paris, his Latin was all his own, his powders were chalk, his mixtures were water, but his remedies to be efficacious had to be taken according to certain particular directions. The rheumatic patient was advised to eat three apples—one at 7 a.m. at the Arc de Triomphe, another at 7.20 in the Place de la Concorde, and a third in the Trocadero Gardens at 7.40. A nervous member of the Stock Exchange, with persistent migraine, was ordered to go to Versailles by the 12.50 to eat an orange, and return by the 2.24—in that way he missed his daily excitement on the Bourse. A lady suffering from intractable insomnia was ordered to take a spoonful of his famous water every half-hour during the night; the nurse had no difficulty with the first two or three doses, but when the fourth was presented the indignant lady insisted on being allowed to sleep! Gruby's therapy was based on using the patient's imagination to reinforce his own pre-eminent common sense, and his astonishing success earned him the odd title of the *derviche guérisseur*. The lecturer next turned to Emile Coué, who was formerly a chemist at Troyes, where his shop window had a battery of flagons, flanked by two splendid bowls, one red and the other blue, with his name in gilt letters above. He observed that the physical and chemical properties of his drugs could not account for all the results obtained by their use, and was clearly one of the disciples of Hippolyte Bernheim, who was practising at the same time with astonishing success at Nancy, demonstrating that healing by automatism was a general phenomenon, not confined to hysteria, as Charcot had taught. Coué's method consisted in making straight a path for the propulsion of sufficiently potent concepts to seize the entire field of the subconscious mind. Auto-suggestion was brought about by the repetition of his celebrated sentence, "Every day in every way," etc., which had to be pronounced without a break twenty times

in succession, using a bit of string with twenty knots as a rosary. In the French the sentence was entirely monosyllabic, and so ran quicker than in the English. Coué soon found that the patients who waited for him created an atmosphere of expectancy. These patients were not given private consultations, they were assembled in a bare room, and the seance proceeded. Coué's cheery good nature was attractive. His self-depreciation disarmed criticism. He used a conversational tone and a simple vocabulary. He stated his principles in few words, and proceeded to test the suggestibility of his patients, making a thrust at any point he wished. The sitting concluded with a short peroration, recited monotonously, a homily of optimistic philosophy, with a few hints on digestion. It was, Dr. Monod said, to a definite category of morbid minds—"mythomaniacs"—that Coué addressed himself. His immediate results appeared to be remarkable. The word "cure" came trippingly to the tongue. But cure might be imagined as easily as disease. In the case of a definite lesion such as a hernia Coué said that the subconscious saw to it that the tear in the peritoneum healed little by little, or, in the case of a fibroid, that the subconscious mind, having accepted the idea that the fibroid must disappear, the brain ordered the arteries which nourished it to contract, so that the fibroid starved. As to malignant tumours, he said only that his method "improved" them. The truth was that what he did was to relieve the patient by removing the anxiety with which the imagination overloaded the lesion. Reduced to the simplest expression, the most implacable of diseases might be induced to create a minimum of reaction. The lecturer discussed the possible harm of Couéism. Coué stated that he advocated only the good use of his method. Yes, but what about others? The method might act both ways. No physician, however, could afford to neglect any kind of successful treatment. He could and would make use of good suggestions. He could learn from Coué. The consulting room of a London specialist always appealed to the lecturer as being sympathetic and optimistic, with engravings illustrating Shakespearean poetry, and furniture suggesting serenity and comfort, and all the technical apparatus disposed behind a screen. It was right to appeal to the imagination, but to rely on auto-suggestion alone was to turn patients into puppets, and the appeal of scientific medicine must be first to the reason. Lord Dawson of Penn, in proposing a vote of thanks, said that beneath the amusing passages of Dr. Monod's address there was a serious warning which the medical profession should take to heart—namely, as to the danger of vanity and pretence. The mind and the imagination must enter into the fabric of disease, and likewise into treatment, and it was for medical men to see that the psychological side of their work was honest, delicate in its application, and incidental in its methods. He spoke also of the harmony of British and French ideals in medicine, and said that Dr. Monod possessed the characteristics of both nationalities in the clarity of his mind, the glow of his enthusiasm, and his genius for friendship. Some excellent exhibits bearing on the subject of the address were shown by the Wellcome Historical Medical Museum.

MAISTRE WACE.

To the vast majority of English readers who have not made a study of Norman-French literature, *Maistre Wace*,¹ as the author—Dr. J. H. Philpot—of the book himself says, must be little more than a name, if so much. Though it is for such readers that this book has been written, it should also earn the gratitude of scholars and of all those who are interested in tracing the origin of English poetry. *Maistre Wace* constitutes one of the bridges over which

¹ *Maistre Wace*. By J. H. Philpot, M.D. London: Methuen and Co., Ltd. 1925. (Cr. 8vo, pp. 155. 7s. 6d. net.)

post-classical poetry had to pass on its way from the memorized to the written word. Dr. Philpot most justly describes him as a pioneer in two literatures and as a forerunner of Chaucer, and, at the present day, of Masefield, to whom the book is dedicated. The life of Wace occupied the greater part of the twelfth century (1110-75). He was born in Jersey, and his father may have taken part in William the Conqueror's invasion of Britain. Educated at Caen in Normandy, much of his life was spent at the court of Henry II and Queen Eleanor of Aquitaine. Wace's main title to fame rests on two long poems in Norman-French. The earliest, 15,000 lines in length, called "Roman de Brut," gives an account of the British kings from Brutus, the first king of Britain, down to Cadwallader. His knowledge was based on the Latin chronicle of Geoffrey of Monmouth, Bishop of St. Asaph, to whom we are indebted for the stories of King Lear, Cymbeline, and the legend of King Arthur. The Latin prose of this old chronicle Wace translated, with considerable additions to it of his own, into Norman-French in octosyllabic rhyming couplets. The book was extremely popular and hailed as a new Aeneid, for the descent of the British kings was traced to the heroes of the Trojan war. The poem was finished in 1155 and dedicated to Queen Eleanor. Five years later the queen commissioned him to write another work, and this was the famous "Roman de Rou," on which his fame as a poet most securely rests, and which induced Henry II to bestow on him the canonry of Bayeux. The poem is a chronicle of the Dukes of Normandy, beginning with Rollo and ending with the battle of Tenchebrai (1105), when the Normans and English finally became united. Hero is recounted how the old viking Rollo, though he had been converted to Christianity, never entirely gave up his pagan habits, so that when he came to die he ordered a hundred Christian throats to be cut in honour of Thor and Odin, while at the same time he showered gifts on the Christian churches! It is in this poem that we have told in 700 Alexandrine verses the strange story of the tragedy of William Longsword, and these Dr. Philpot has translated for us in lucid and vigorous verse, while he has also unraveled the very tangled political skein of that epoch. It must be remembered that Wace was writing towards the end of the Dark Ages, when something of an early renaissance may be detected, "the rude strength of the Middle Ages turning to sweetness"; it was a time when men were beginning to love the things of the intellect and the imagination for their own sake. Dr. Philpot exhibits Wace as a very human, somewhat worldly person, who thoroughly enjoyed his life at the court and dearly loved making money. His muse was rather a pedestrian one, and perhaps his merit may be greater as an historian than as a poet; he was less the inspired artist than the careful craftsman, who worked conscientiously at his materials; but Wace fully realized the value of his own writings, as is shown by the following:

How long shall any name resound
Beyond the grave unless 't be found
In some clerk's book; it is the pen
Gives immortality to men.

A NEW BIOLOGICAL JOURNAL.

The first appearance of the *Quarterly Review of Biology* adds yet another to the approximately 25,000 reputable scientific journals published at regular intervals, and it is fitting that in the first sentence of this new periodical Dr. Raymond Pearl, the editor, should ask the question, Why start another? He replies that it is the purpose of the new journal to keep scientifically minded readers informed of progress in all branches of science, and is addressed to "a fairly numerous body of cultivated men and women who are genuinely interested in knowing about the progress which biology is making." The first number contains articles on the

biology of the mammalian testis and scrotum, symbiosis among animals, with special reference to termites and their intestinal flagellates, experimental studies on morphogenesis in the nervous system, a review of the discovery of photoperiodism, and the influence of the length of daily light periods upon the growth of plants, and recent discoveries in the biology of amoeba. The articles are fairly short but comprehensive, and are written so far as possible in non-technical language, so that teachers, investigators, and others who are not actively engaged in research but who are interested in biology in its broadest sense may be able readily to understand papers by specialists working in other fields. An interesting series of papers is promised for future numbers. The editor has the assistance of an advisory board of experts in different branches of biology, most of them occupying teaching posts in American universities. The journal will certainly justify its existence if future numbers are as interesting as the first. It is published by the Williams and Wilkins Company of Baltimore, U.S.A., and the London agents are Messrs. Baillière, Tindall and Cox, 8, Henrietta Street, Covent Garden, W.C.2. The price is stated as 5 dollars a year, or 1½ dollars a copy.

TETRA-ETHYL LEAD.

ATTENTION was drawn a year ago in these columns¹ to the possible danger to the public involved in the addition of one part in a thousand of tetra-ethyl lead to petrol to make the product ethyl gasoline. The numerous cases of poisoning associated with the manufacture of tetra-ethyl lead in large quantities disquieted the United States public health officials, and a conference was held last May to discuss the effect of the use of ethyl gasoline on the public health. As a result of the report of the conference the manufacturers discontinued the sale of ethyl gasoline, of which 300 million gallons had already been distributed. A committee appointed by the conference has just reported.² Its conclusions are that, although ethyl gasoline has been used for two years by some drivers of cars, yet it is unable to find any evidence that the use of ethyl gasoline has caused any lead absorption in drivers of cars. Employees at garages were found frequently to suffer from slight lead poisoning, but this occurred in garages where ethyl gasoline was not used, although it was more marked when ethyl gasoline was used. The committee concludes that there is no valid reason why the sale and use of ethyl gasoline should be prohibited, but it recognizes that its conclusions are based on a relatively small number of cases studied over a relatively short period. Lead is a particularly dangerous poison owing to its extraordinary power of producing cumulative effects, and it is to be hoped that the subject will be very fully investigated before any general use of ethyl gasoline is allowed. Owing to this property of lead it is obvious that very extensive and irreparable damage might be produced before the first symptoms of poisoning appeared.

² Journ. Amer. Med. Assoc., 1926, 86, 370.

EXPERIENCE shows that it is difficult to keep up the interest in a debate for much more than an hour at a time. It is also well known that when a debate is adjourned to a subsequent day the interest in it flags. The Royal Society of Medicine last week made a successful experiment in overcoming both these objections. The discussion on the diagnosis and treatment of intrathoracic new growths united in debate the Sections of Medicine, Electro-Therapeutics, Surgery, and Laryngology, under the presidency of Dr. Hugh Thursfield. A profitable discussion, as our report shows, was in full swing from 5.30 to 7.15. The meeting then stood adjourned for half an hour, when a welcome break was utilized for obtaining refreshments at a buffet organized by the society and at a very nominal price. The debate, after this half-hour's rest and refreshment, was then carried on with renewed zest until 10 o'clock. Many more Fellows would doubtless have profited by this arrangement had it been advertised beforehand.

New South Wales.

[FROM OUR SPECIAL CORRESPONDENT.]

UNIVERSITY OF SYDNEY.

MR. A. RADCLIFFE-BROWN, professor of social anthropology in the University of Capetown, has been appointed to the newly created chair of anthropology in the University of Sydney. The senate acted upon the advice of a committee consisting of Professor J. T. Wilson (Cambridge), Professor Elliot Smith (University College, London), and Dr. A. C. Haddon (reader in ethnology, Cambridge). The establishment of the chair was made possible by the action of the Commonwealth and the several State Governments—on the strong recommendation of the Australian National Research Council and the universities and scientific bodies in the various States—in providing sufficient funds for the upkeep of the department. Professor Radcliffe-Brown has been engaged in anthropological field work for the past sixteen years in the Andaman Islands, Australia, and South Africa. He was a scholar of Trinity College, Cambridge, and after taking his degree was awarded the Anthony Wilkin studentship to make investigations among the Andaman islanders. He published an essay on the religion of the islanders in *Folk Lore*. He became a Fellow of Trinity College, and the next piece of field work he undertook was in north-western Australia in 1910; it yielded important results, some of which were recorded in *Man*, 1910, 1912, 1914. In addition, Mr. Radcliffe-Brown has published a monograph on the "Andaman Islanders." He was president of the Section of Anthropology of the South African Association for the Advancement of Science, and while in Capetown established a successful department of anthropology and greatly stimulated interest in anthropology, the number of undergraduates in the subject having grown from sixteen in 1922 to forty-four in 1924, some of whom were working for master's and doctor's degrees in anthropology.

Associate Professor A. N. Burditt has been appointed to the Challis chair of anatomy at the University of Sydney. He has been on the teaching staff of the university since 1919, when he was lecturer and demonstrator of anatomy. In 1924 he was appointed associate professor of anatomy while he was prosecuting researches in Europe. The present appointment has been made after consultation with a committee in London, consisting of Professor J. T. Wilson, Professor G. Elliot Smith, and Professor C. J. Martin. Professor D. A. Welsh, professor of pathology, has been appointed dean of the Faculty of Medicine in succession to Dr. A. E. Mills, the professor of medicine, who has been granted a year's leave. Dr. S. A. Smith has been appointed acting professor during his absence.

A Bequest to the University of Sydney.

The late Colonel Oswald Watt, who died in May, 1921, left estate valued for probate purposes at over £175,000. The testator bequeathed the bulk of his property upon trust to the Senate of the University of Sydney "for such uses for the benefit of the institution as the Senate in its absolute discretion should determine." The trustees have now informed the university that the great part of the estate has been realized, and that after realization of some further assets and the death of certain annuitants, a sum approximating to £109,500 (of which £46,000 has been already paid over) will ultimately be received by the university.

ROYAL PRINCE ALFRED HOSPITAL.

During 1924-25 the number of patients under treatment was 8,250. Of these, 4,800 were discharged cured, 2,001 were relieved, 577 unrelieved, and 370 died. The average number of patients resident daily was 493.9; the mortality rate over total cases under treatment (deducting 74 deaths of patients within twenty-four hours of admission) was 3.58 per cent.; the attendances in the out-patient and casualty departments numbered 127,947. The total revenue from all sources was £103,060, as compared with £100,379 in the year 1923-24, while the expenditure was £111,857, as compared with £111,884, the excess of

expenditure over revenue having thus been £8,797, as compared with £11,504. The revenue fell in donations (from £2,777 to £2,440), but there was a marked reduction in income from the Repatriation Department, owing to the lower numbers of patients treated; which fell from £17,043 to £12,556. In nearly every other respect the income was higher than in the previous year, the total from public contributions having risen from £11,213 to £15,060; from patients other than repatriation cases from £11,306 to £12,200; from miscellaneous receipts from £8,287 to £9,434; and from extraordinary receipts (legacies and bequests not invested) from £630 to £1,012.

ROYAL ALEXANDRA HOSPITAL FOR CHILDREN.

The Royal Alexandra Hospital for Children has been recognized by the University of Sydney, upon the recommendation of the Faculty of Medicine, as a clinical school for the training of medical students in the diseases of infancy and childhood. The students will attend daily in groups for a period of six weeks each, and during such time will not be permitted to attend the general hospital to which they have been attached. The number of patients treated in the hospital in 1924 was 40,790. Of these, 8,332 were treated as in-patients in the main hospital; 14,980 casualty and out-patients were treated in the casualty department; and 17,325 were treated in the out-patient department, Quay Street. The average number of beds occupied daily was 290, and the average cost of each occupied bed was £160. In the convalescent home at Collaroy Beach 153 in-patients were treated, the average cost per occupied bed being £111. The expenditure of the hospital in 1924 amounted to £61,390, and the ordinary receipts for the same period to £58,588.

Scotland.

THE ROYAL HOSPITAL, MORNINGSID.

In his report for 1925, the hundred and thirteenth since the opening of the institution, Professor G. M. Robertson, the physician superintendent, deals with several questions of the utmost moment in regard to the treatment of mentally disordered patients. As is well known, Professor Robertson has for long fought to free the mentally sick from the hindrances and harsh obligations imposed by the lunacy laws.

"The carefully designed and elaborate procedures for the protection of the liberty of the subject are considered in these days superfluous; more than that, they are inimical to the peace of mind and well-being of sick patients needing treatment, whatever the legal mind may say in their favour. Although they deal with the healing of the sick, a medical spirit is conspicuous by its absence in our lunacy laws."

Professor Robertson hopes that those in authority have noted that patients, the relatives of patients, and the medical profession are opposed to the present system of certification and of sheriffs' orders. This attitude is reflected in the increasingly high percentage of those entering for treatment as voluntary patients; this is a particular feature of the admissions to the hospital at Morningside. In Scotland any patient who understands what he is doing can enter a mental hospital for treatment as a voluntary patient merely by signing an application expressing his or her desire to do so. This applies to the poor as well as to those with means, and parish councils are becoming more and more willing to concede the privilege to those who are chargeable, although by doing so they incur some additional expense.

Nursing Homes.

In addition to Craig House and West House, in which private patients are treated and cared for, the managers have established, during the last seven years, a third department quite apart from the two mentioned—namely, a group of nursing homes in the suburbs of Edinburgh in which physicians can visit and treat their own patients exhibiting nervous or mental symptoms, exactly as they visit and treat those with bodily diseases in ordinary nursing homes. Each of these nursing homes is specially

adapted for a certain type of case, and this differentiation adds to the value of the group. They have enabled many persons suffering from mild or transient attacks of mental disorder to be treated and to recover without certification or being placed in a mental hospital.

The Royal Hospital and the Royal Infirmary.

Professor Robertson again lays stress on the necessity of co-operation of the mental physician with the general physician in the treatment of patients suffering from mental ailments, and points out that the benefit derived from such co-operation is reciprocal. In recognition of this trend towards co-operation, and of the growing importance of the subject, the managers of the Edinburgh Royal Infirmary two years ago appointed the physician superintendent at Morningside physician consultant in psychiatry at the Infirmary. They have now decided to authorize the opening of a mental out-patient clinic to be conducted by him with the help of two assistants; it began work on March 2nd, and will be held weekly. It will be purely for out-patients, and has not the privilege of recommending a patient for in-treatment. To make good this deficiency the managers of the Royal Hospital at Morningside intend to provide an observation hospital situated near the West House for the treatment of early and mild forms of mental trouble among patients of the classes who, for bodily ailments, seek admission to the Royal Infirmary. It is to be called the Jordan Burn Hospital, and will not be a mental hospital or an asylum, but will be actually a hospital for a special form of disease, into which all patients enter voluntarily and without any legal formality or stigma, exactly as they do when entering the wards of the Royal Infirmary. The difficulty to be faced in this is financial, and an appeal is made to the generosity of the public, £15,000 being the amount required. The benefits to the poor of such an observation hospital are wellnigh incalculable.

EDINBURGH ROYAL INFIRMARY IN 1925.

The annual report of the Royal Infirmary of Edinburgh for the past year shows that 15,755 patients were treated in the institution, an increase of 68 over the number of the year before. The largest number of in-patients on any one date was 943, and the average duration of stay 20.6 days. Excluding the deaths which took place within forty-eight hours after admission, the death rate was 4.7 per cent. Besides the cases treated in the wards, 55,346 out-patients attended, being an increase of 6,907 over those receiving treatment in the preceding year. The average waiting list of persons desiring admission to the wards was 1,932, of which number 812 were ear, nose, and throat cases. With regard to finance, the ordinary income was £109,931, as compared with £107,907 for the preceding year, or an increase of £2,023. As compared with this, the ordinary expenditure had been £127,751, an increase of £214 over that of the preceding year; but as it was pointed out that there was an average of two more beds in daily occupation throughout the year, the relative expenditure was really under that of 1924. The extraordinary income amounted to £75,020, while the extraordinary expenditure amounted to only £3,751, so that the deficit of ordinary income and expenditure is amply met, and £15,317 retained as part of the permanent capital. The cost per occupied bed for the year was £141 3s. 3d., or 1s. 6d. less than that for the previous year. A special badge day collection in the city and provincial districts on May 23rd resulted in the collection of £7,419, an increase of £1,347 over the sum derived in the previous year from a similar source. This fund is raised largely by a pageant, organized by a secretary assisted by a large and representative citizens' committee, and various friendly societies, trade union organizations, and industrial firms and business establishments take part in it by arranging attractive displays. The total amount raised by this means since its inauguration ten years ago is £44,580. A systematic scheme for collecting small subscriptions from the employees of public works, business establishments, staffs of schools, banks, Government and other offices, known as the League of Subscribers, yielded during the year £21,356 (£451 more

than the previous year); there are 1,021 groups of subscribers in Edinburgh and 373 groups in provincial districts. The leading contribution is that of the London and North-Eastern Railway Company's employees (North British Railway section), whose subscriptions during the year reached the sum of £2,490. The contributions from miners and oil workers, made through the pay office staffs of the various collieries and works, amounted to £14,348 during the year, a decrease of £593 as compared with the previous year. This falling off was fully accounted for by the continued trade depression and resultant unemployment in the mining industry.

ROYAL MEDICAL SOCIETY OF EDINBURGH.

The annual dinner of the Royal Medical Society of Edinburgh was held in the Hall of the Royal College of Surgeons of Edinburgh on February 25th. The Senior President, Dr. J. G. McCrie, presided, and the guest of the evening was Dr. James Taylor, C.B.E., physician to the National Hospital for the Paralyzed and Epileptic, Queen Square, London. Among those present were Sir James Hodsdon; Sir Harold Stiles; Professor John Fraser; Emeritus Professor W. Russell; Professor R. Muir; Dr. John Orr, dean of the Faculty of Medicine, Royal Colleges; Dr. John Stevens, honorary secretary of the Edinburgh Branch of the British Medical Association; Dr. R. W. Johnstone, President of the Edinburgh Obstetrical Society; Dr. W. Guy, dean of the Dental School; and Dr. O. Charnock Bradley, Principal of the Royal (Dick) Veterinary College. After the usual royal toasts had been acknowledged, that of the Imperial Forces was proposed by Mr. M. A. T. Thomson, Master of the Merchant Company of Edinburgh, and acknowledged by Captain J. Tovey, R.N., and Lieutenant-General Sir W. E. Peyton, K.C.B., G.O.C. Scottish Command. The chairman, in proposing the health of Dr. James Taylor, welcomed him as an old president of the society as well as on account of his eminence as a physician. Dr. Taylor, in proposing the toast of the Royal Medical Society, recalled with infinite pleasure the happy evenings which he had spent as a student in the society's old hall in Melbourne Place. He thought that the members of the medical profession were justified in the opinion they held that their profession was the best profession of all. It offered a great deal, for it presented scope for intellectual endeavour, constant interest, and its boundaries were always widening. He had recently taken part in a discussion with some well known medical friends—as to the quality which was chiefly responsible for success in medical practice. On taking a vote, it was found that each of them had expressed the opinion that the quality which conduced mainly to this was that of sympathy. In addition to the scope it offered for intellectual pleasure and exercise, medicine had a strong human appeal. Mr. W. R. Russell, one of the presidents of the society, in reply, said that the society was in a flourishing condition, and during the present session its active membership had increased from 99 to 119. The society's library was becoming more widely used after the period of depression during the war, and the Library Committee contemplated purchasing many more books. He believed that the society continued to maintain its old tradition and was an important adjunct to medical education in Edinburgh. Dr. R. H. Sanderson, also a president of the society, proposed the Edinburgh Medical School, and remarked that the bicentenary of the Medical Faculty of the University would be celebrated in the present year. Professor G. M. Robertson, President of the Royal College of Physicians of Edinburgh, replied on behalf of that body, and Dr. A. Logan Turner, President of the Royal College of Surgeons, for that corporation. He believed that so long as the teachers in the Edinburgh school maintained the tradition of making teaching the first call on their time, so long would Edinburgh maintain its position as a great medical school. In referring to the beginnings of the school, he mentioned in particular three names—those of Sir Robert Sibbald, Dr. John Monro, and Provost George Drummond, who had been responsible for the virtual founding of the institutions upon which the beginning of an efficient medical school in Edinburgh had depended. To

Sir Robert Sibbald the city was indebted for the commencement of a scientific outlook upon medicine. Dr. John Monro had been the first to conceive a complete medical faculty in which all the subjects then necessary for medical education should be taught, and he had educated his brilliant son, Alexander Monro, with the object of teaching anatomy and of organizing such a faculty. To Provost George Drummond the movement which had resulted in the founding of the Royal Infirmary was to be credited. Dr. L. B. Wevill, another president of the society, proposed the sister professions of the Church and the Law, to which the Rev. Dr. James Harvey, Moderator of the General Assembly of the United Free Church, and Sheriff McClure, K.C., replied.

RELIEF OF INCURABLES.

The fifty-first annual meeting of the Association for Relief of Incurables in Glasgow and the West of Scotland was held on February 24th in the Merchants' House, Glasgow. Lord Provost Sir M. W. Montgomery presided. The total number of patients during 1925 had been 333, of whom 142 had been treated in Broomhill Home, 65 in Lanfine Home, and 126 in the outdoor relief department. During the year the oldest inhabitants in point of residence at both homes had died—one in Broomhill after a stay of forty-eight years, and the other in Lanfine after twenty years. These long periods, although passed in weakness, had not been spent in idleness, for both patients were experts in certain handicrafts. The association had depended for its success largely upon the contributions from employees of public works, and subscriptions from this source had shown an increase. Dr. R. M. Buchanan, president of the Royal Faculty of Physicians and Surgeons of Glasgow, in moving a resolution of thanks to the subscribers, said that the relief of incurables had always made a strong appeal to the liberality of citizens in the West of Scotland. The number of patients suffering from the effects of rheumatism and of tuberculosis was striking. On the prevention and cure of these two diseases medical science was at present concentrating attention, and a valuable adjunct to the association would be provision for research in regard to these diseases. The homes provided opportunities of a most favourable kind for such work.

GLASGOW EYE INFIRMARY.

At the hundred and second annual meeting of Glasgow Eye Infirmary, held on February 22nd, the Lord Provost, Sir Matthew W. Montgomery, who presided, said that the hospital was one of the most beneficial institutions in the city. During the year 1,791 patients had been admitted, and there had been a total attendance of 67,577. The ordinary income did not meet the ordinary expenditure, and it had been necessary to draw on capital account to make up the deficiency. An important phase of the work was the attention given to infantile affections of the eye; for the fact that the number of children now developing blindness at birth was a negligible quantity, the Eye Infirmary was entitled to a great share of the credit.

ABERDEEN ROYAL MENTAL HOSPITAL.

Occupational therapy was commenced at the Aberdeen Royal Mental Hospital during 1925, and in the annual report for the year it is stated that it has been found to be of definite value, not only for convalescents, but also when progress towards recovery has ceased. A considerable variety of employment is available, and stress is laid upon the importance of this, so that the greatest number of patients may be influenced. In some melancholic and demented patients interest gradually developed, both in the work they were themselves able to do and also in that of others. With increasing interest came greater ability, until such articles as rugs and baskets were manufactured; the workmanship of nearly all the articles was of a surprisingly high standard. Dr. R. Dods Brown, the physician superintendent, states that recovery was hastened in many cases in this way, and improvement effected in patients who had been inmates for a long time. It is now proposed to erect five or six verandahs for the open-air treatment of patients.

England and Wales.

VOLUNTARY HOSPITALS COMMISSION.

THE Minister of Health has addressed a letter to the chairman of the Voluntary Hospitals Commission explaining that he has come very reluctantly to the conclusion that in the present financial situation it is impracticable at this stage to proceed with the proposals made in the Commission's last report for a parliamentary grant towards the cost of hospital extensions. In expressing his appreciation of the services of the Commission, Mr. Chamberlain has informed Lord Onslow that he is most anxious that the Commission should continue its work, both to act as a link between the Government and the voluntary hospitals, and also to keep in touch with the local voluntary hospital committees throughout the country and to facilitate communication between them. It is understood that the chairman has intimated to Mr. Chamberlain the willingness of the Commission to comply with this request.

THE ROYAL NATIONAL ORTHOPAEDIC HOSPITAL.

A festival dinner of the Royal National Orthopaedic Hospital, in Great Portland Street, was held on February 24th at the Hotel Victoria, with H.R.H. Prince Henry, K.G., the president of the hospital, in the chair. The dinner was organized to further an effort which the hospital is making to provide 200 additional beds and to extend the out-patients' department. Mr. H. E. West, chairman of the committee appointed by Prince Henry for the purpose of raising the necessary funds, reported that the sum desired was £87,500, and that so far £40,000 had been received. The extensions at Great Portland Street were now well under way, and it was hoped soon to start the first unit of the extension at Brockley Hill, Stanmore, where a country branch was opened in 1922. Prince Henry, in commending the charity, said that it began its work in 1838, and had turned hundreds of thousands of actual or potential cripples into healthy, happy, and useful members of the community. The hospital was still far too small for the increasing demands upon it. Twenty years ago it had only 45 beds, to-day it had 300, and the out-patient attendances annually had multiplied during the same period by more than seven. To-day there was a waiting list of a thousand children. The hospital dealt with both the preventive and curative sides of orthopaedic surgery. Its surgical staff included the greatest names in that branch of science. In view of the prolonged character of the treatment, educational facilities had to be provided for the child patients, and both at Great Portland Street and Stanmore the hospital had a school, staffed by fully qualified teachers. His Royal Highness thought there were few charities which came so near to the heart of humanity as the care of the crippled. The Spanish Ambassador also made an eloquent plea on behalf of the hospital, and referred to the influence of British orthopaedists in European countries. He also described the antituberculosis and similar movements in Spain, which, he said, owed their inspiration chiefly to the British princess who was the Spanish queen. Mr. Reginald McKenna, treasurer of the hospital, pathetically appealed to the company and the public not to allow him, in his capacity as treasurer, to be numbered among the unemployed. Other speakers were the Earl of Denbigh, the Bishop of St. Albans, Major-General the Right Hon. J. E. B. Seely, and Lord Riddell. At the end of the dinner Prince Henry announced that an additional £7,500 had been subscribed at the tables.

VENEREAL DISEASE AND THE MERCHANT SERVICE.

The British Social Hygiene Council held a meeting at the County Hall, Westminster, last week to consider what recreational facilities could be provided in the Port of London. Mr. Greaves-Lord, M.P., who was in the chair, drew attention to the material difficulties in securing continuous curative treatment in the case of seamen, and in spreading knowledge effectively. Seamen on arriving in port were, he said, subjected to intensified temptation.

The British Social Hygiene Council, he felt, would be lacking in a most important part of its work if it did not teach that cleanliness of thought and continence were the only preventives of disease. While much could be done by education, the men on landing desired companionship, and if this was not provided they would seek it in undesirable ways. It should be remembered that the sailor had the same instincts for sport as other people, and these should be exploited. Mr. Cuthbert Laws said that the council had set its hand to a great work, and suggested that the local authorities should be invited to co-operate—as, for instance, by providing open spaces for the use of seamen. London had been very generous to seamen who visited the port, but there was need for opportunities for healthy recreation on shore, and it might be possible to secure greater co-ordination of such facilities as did exist. The shipowner would welcome anything that tended to induce a healthy mind in a healthy body. Mr. Leonard Bowden, representing Mr. Havelock Wilson, reminded the conference that in the earliest log-book in the world sirens had attempted to lure the crew of Ulysses to destruction, and to-day there were harpies in every port. He urged the council to build on the foundations that had been laid by those who knew the seaman, and to federate the various clubs existing for his welfare. Municipalities, banks, and other organizations had playing-fields which might be placed at the disposal of seamen. London should take the lead in providing facilities for uplifting a fine body of men. Mr. E. B. Turner held that by opportunities of exercise and sport the tendency to kick over the traces was greatly reduced. He said that in one command, as a result of organized games, venereal disease had dropped from 327 per thousand in 1885 to 30 per thousand in 1914, because the boys had worked off their superfluous energy in playing games instead of playing the devil. The whole period from 1872 to 1914 had been characterized by a less general consumption of alcohol, by the prohibition of public solicitation, and by the revival of athleticism among all classes. Already he saw signs that the practical standard of morality was rising, and the objective should be to extend this improvement to sailors. Fleet-Surgeon W. E. Home cited the case of Singapore, where at one time the incidence of venereal disease had been 50 per thousand a month. Recreation of all sorts had been introduced, and by February, 1925, there was not one case per thousand a month. Admiral Tupper said that the municipalities should provide playing facilities, and pleaded for young men who were athletes to go on board ship and say to the seamen, "Come along, we want a game." Mrs. Neville Rolfe announced that the conference was the first of a series that was to be held in the main ports of the British Isles. Women should be got to open their homes to other people's sons when they came into port. The mercantile marine added to the wealth of the port, and the seaman therefore had a claim upon the port. She insisted that the seaman had an equal right with the resident to the use of the open spaces, and advocated the organization of retired officers and men resident in port towns who should have facilities given them by the owners to get in touch with the ships when they reached port. After Mr. Hall Hall, chairman of the London Playing Fields Association, had expressed the hope that wealthy people connected with shipping would provide grounds for seamen visiting the Port of London, a resolution was passed nominating representatives of the chief interests concerned with instructions to draw up a concrete scheme for providing recreational facilities for seamen in the Port of London.

RESEARCH ENDOWMENT AT THE LONDON HOSPITAL.

A recent anonymous gift of £50,000 to the London Hospital for the endowment of research into the causes of disease has been invested in trustee securities with the object of providing salaries for research workers. The donor of this sum signified in August last his desire to make the gift, and as a result of many conversations as to the best channel for such benevolence he accepted the suggestion of the hospital authorities to endow medical research. It was explained to him that research was badly handicapped in this country because, unless a man had means of his own, he was rarely able to take up research as

his life-work. He might exist on a miserable honorarium, or keep himself going for a year or two by means of scholarships; but as domestic responsibilities came he had to abandon the work for more lucrative employment, thereby often scrapping a piece of research when it was becoming valuable. A trust deed accordingly was drawn up, requiring the dividend to be spent on salaries, not on buildings or on laboratory equipment, which it was thought the hospital itself should provide. The fund, which is to be known as the Freedom Research Fund, is to be managed by a committee consisting of a nominee of the donor, the head of the clinical laboratory, and the house governor of the hospital. The following dispositions have been made: (1) a scholarship in pathology of £100 a year, open to students, selected by examination, from Oxford and Cambridge; (2) a research studentship of £400 a year, tenable for three years, the student to devote his whole time to a subject chosen for him; (3) the remainder of the income to be divided between two senior pathologists who will devote their whole time to research work of their own choice. By the annual scholarship for junior men it is hoped to keep in touch with those who have a leaning towards research, and to give such men the opportunity of showing their capacity in the laboratories attached to a great hospital. The research student will act as an assistant to one of the senior research workers; to this post Mr. Leslie Hewitt, recently working with the Medical Research Council, has already been appointed. The two pathologists for the senior positions are to be Dr. S. P. Bedson, of the Lister Institute, and Dr. W. Howard Florey, at present John Lucas Walker Scholar of Cambridge University and working in America under the Rockefeller Foundation. The researchers will have the very great advantage of working in extremely fine laboratories—the Hale and Dunn laboratories of the London Hospital—side by side with the hospital staff who are doing the routine investigation work; they will be in touch also with the clinical work of the hospital, and especially with the medical unit, and they will be working in a centre where unlimited clinical material is forthcoming. The sum of £50,000 does not represent the limit of the endowment fund which it is hoped to reach.

CUMBERLAND INFIRMARY.

The rapid progress now being made by the Cumberland Infirmary was described at the annual meeting of subscribers held on February 13th, when the president, Mr. T. Carr, presented the eighty-fifth annual report of the committee of management. As compared with the previous year the number of in-patients had increased by 399 during 1925, and the out-patients by 516, the respective totals being 2,312 and 7,394; all the wards had been fully occupied. The income for the year, including legacies, had been £16,485, and the expenditure £13,271, resulting in a gratifying balance of over £3,000; there were now twenty-seven endowed beds and eight endowed cots. Considerable progress had been made in the erection of the new out-patient department, and it was hoped that the building might be completed and occupied during the current year. Further ward accommodation was urgently needed, but this would necessitate an increase of the staff accommodation and a complete reorganization of the administrative department, with a considerable increase in the cost of maintenance. During the year the committee had made an arrangement with the Silloth Convalescent Institution which it was hoped would result in many more infirmary patients being sent there for convalescence. The chairman made special reference to the presidential address of Mr. Norman MacLaren to the Border Counties Branch of the British Medical Association last year. Besides giving a most interesting history of the Cumberland Infirmary, eight proposals for its extension were outlined in it. Of these only two had been dealt with so far—the provision of an electric lift and the work on the new out-patient department. The six remaining projects were at present held up, mainly for financial reasons. A chart had been prepared which showed that since its establishment in 1840 the infirmary had grown to five times its original size, and it

was indicated that any further enlargement of the buildings must be accompanied by a corresponding increase in revenue. The Voluntary Hospitals Commission had reported that 10,000 additional hospital beds were required for England and Wales; the proportion applicable to the Cumberland Infirmary would be twenty beds to be added during the next five years. The chairman added that the new out-patient department was being constructed in such a way that another story could later be erected on the top, and that possibly the additional beds might be obtained.

MATERNITY AND CHILD WELFARE: BIRMINGHAM MEETING.

The first provincial meeting of the Maternity and Child Welfare Group of the Society of Medical Officers of Health was held in Birmingham on February 19th and 20th, under the presidency of Sir John Robertson, M.O.H. Birmingham. Dr. Ethel Cassie contributed a paper on some aspects of child welfare work in the United States of America and Canada, and referred to the large and extremely efficient part played by voluntary agencies in infant welfare organization in various towns she had visited. Active propaganda by posters and literature was employed on a far larger scale than in this country, and was undoubtedly very beneficial. There were apparently in America no specifically trained midwives, and the practising midwife had no legal status. Miss Hilda Shuffelbotham gave an account of defective ante-natal care and defective obstetrics, with special reference to the health of the mother. She recommended a routine post-natal examination at the end of the puerperium as a preventive of later gynaecological trouble. Visits were paid to various heliotherapy centres and to the Carnegie Institute, where an exhibition dealing with all aspects of infant welfare work was explained in detail by the Institute's staff.

BRISTOL CONGRESS OF PUBLIC HEALTH.

Under the auspices of the Royal Institute of Public Health a congress will be held at Bristol, from May 19th to 24th, under the presidency of the Duke of Beaufort, High Steward of the City of Bristol. The congress will include sections of State medicine and municipal hygiene; naval, military, air, and tropical diseases; industrial hygiene; pathology, bacteriology, and biochemistry; and women and the public health. For May 19th a reception has been arranged by the Vice-Chancellor of the University of Bristol, and the congress dinner will be held on May 20th. In connexion with the meeting excursions are being arranged to Bath, Cheddar, Wells, and Glastonbury, and a church service on May 23rd. The Ministry of Health has intimated that it will be prepared to sanction the reasonable expenses of two delegates to the congress from those local authorities in England and Wales whose accounts are subject to Government audit. Further information may be obtained from the secretary of the Royal Institute of Public Health, 37, Russell Square, W.C.1.

SUNDERLAND ROYAL INFIRMARY EXTENSION.

On February 24th H.R.H. Princess Mary (Viscountess Lascelles) visited Sunderland to lay the foundation stone of the Royal Infirmary extension. The origin of the present infirmary was a dispensary, which was established in May, 1794. Changes of site have been made from time to time, and expansion had been necessitated by the increasing population of the town; the number of people served by it now is about 350,000. The institution was one of the first in the country to organize the collection of contributions from workpeople, and it abolished the ticket system of admission in 1855, since when the only qualification for admission has been medical or surgical necessity. Previous extensions had been made in 1867, in 1882, in 1888 when an out-patient department was added, and in the early nineties when the Hartley wing was opened and an isolation block completed. A convalescent home, mainly for children, was provided in 1891, and in the following year a home at Harrogate, which now accommodates forty patients. An important extension was made in 1903, when the building of the children's hospital was begun. During the war nearly 3,000 wounded received treatment. In 1917 the venereal diseases department was opened, and in 1921 a modern orthopaedic department. In 1922 the pathological department began work; in addition to serving the needs

of the infirmary and children's hospital, it deals with a large amount of the public health work of the town and district. In 1923 a new operating theatre block and an x-ray department were added. The present extension scheme comprises the building of two new three-storied ward blocks, the rebuilding of the administration block, enlargement of the out-patients' department, and the provision of accommodation for paying patients. The new administration block will be four stories high, with workshops and kitchens on the lower ground floor, and matrons' rooms and rooms for the medical and nursing staffs on the upper floors. Each ward block will be three stories in height, with accommodation for 95 beds, and on each floor there is to be a large ward with a balcony at the south end. On the ground floor a large glass-roofed sun balcony will be placed on the west side of each ward. The out-patients' department will be brought thoroughly up to date, and special provision made for ear, nose, and throat cases. The estimated cost of the completed scheme, exclusive of furnishing, is approximately £150,000, and the accommodation will be increased from 240 to 480 beds.

THE LONDON COUNTY COUNCIL AND ARTIFICIAL LIGHT TREATMENT IN TUBERCULOSIS.

The London County Council has been making arrangements for the experimental use of artificial light under specialized supervision in the treatment of tuberculosis in the various boroughs. To this end negotiations have taken place with the authorities of certain London hospitals. It is proposed that the metropolitan borough councils should be enabled to arrange on an experimental scale for a period of twelve months, as part of their tuberculosis dispensary schemes, for artificial light treatment in the out-patient departments of certain hospitals and other approved centres. The arrangements will be made direct between the borough councils and the hospital authorities, and will be subject in each case to approval by the Minister of Health (who has already given the scheme a general approval) and the L.C.C. It remains to be seen to what extent the borough councils take up the scheme, but on the assumption that 1,600 cases will receive treatment in the year the cost is estimated at £2,400.

Correspondence.

PUERPERAL FEVER: ENDOGENOUS INFECTION.

SIR,—As the interim report on the causation of puerperal morbidity and mortality¹ is under consideration I should like to indicate one aspect of the question of "endogenous infection." The report says:

"The possibility of endogenous sources of infection has been suggested from time to time, but has not met with acceptance by that section of the profession still dominated by the views of Semmelweis."

Is it possible that any section of the profession refuses to believe that a woman can have her pelvic organs infected from the bowel or by the blood stream soon after a labour or an abortion? If so, its position is surely opposed to the dictates of common sense.

In ordinary gynaecological work there are plenty of cases of pelvic peritonitis, tubo-ovarian abscess, and acute recurrent attacks of pelvic inflammation in which no one would suggest that the infection had just arrived from the outer world by the vaginal route. Dermoid cysts, ovarians with twisted pedicles, fibroids with impaired blood supply, and other structures often get infected from the bowel or by the blood stream. What is there peculiar to the puerperal state which can prevent occurrences such as these? On the other hand, the pelvic structures are often bruised during labour, and are thus more likely to be infected from endogenous sources during the puerperium than they are at other times.

Thus, logically, we should expect to meet with pelvic inflammatory lesions of endogenous origin following labour. And clinical experience bears out this expectation. We do.

—I am, etc.,

Manchester, March 1st.

W. E. FOTHERGILL.

¹ BRITISH MEDICAL JOURNAL, SUPPLEMENT, January 8th, 1925.

SYSTEMIC FACTORS IN CANCER.

SIR,—Dr. Cramer, in a recent British Medical Association Lecture (BRITISH MEDICAL JOURNAL, January 30th, p. 175), drew attention to the observation of Dr. Murray that the production in mice of a tumour of the skin by tarring at one site produces a resistance to its development at another site.

Since the publication of Dr. Murray's paper I have collected from the records of the Cancer Hospital more than twenty-five cases, verified microscopically, of multiple primary human cancer to elucidate this point, a number of which come within my own experience. The numbers are, no doubt, too small to have any statistical value, but, so far as they go, they do not seem to support Dr. Murray's theory.

Dr. Cramer also refers to the experiment of the removal of mammary cancer in mice, followed by tarring, in which a similar resistance to the development of growth on the skin was found. I have the records of several cases of carcinoma of the breast or other organs removed successfully some years previously, in which cancer of another type developed subsequently at another site. The number of these cases is not large, but this is partially accounted for by the difficulty of tracing such cases, and by the fact that the average duration of life after operation for cancer of the breast, as shown by Dr. Wyard from the records of this hospital, is not more than five years. It may be mentioned further that the recent experiments of Lynch at the Rockefeller Institute on the ablation of mammary carcinomata in mice followed by tarring do not support Dr. Murray's theory of resistance.

Dr. Greenwood (February 13th, p. 302) points out that there is no statistical evidence that the causes which favour the development of one form of cancer hinder the development of another form, and it seems possible that the reason is that no such hindrance exists in the human subject.—I am, etc.,

London, Feb. 24th.

H. J. B. FRX.

THE ACTION OF CERTAIN ALLEGED INTESTINAL ANTISEPTICS.

SIR,—Dr. Garröd deserves the thanks of our profession for his article on the above subject, published in your last issue (February 27th, p. 367), and for the moderate statement of the conclusions which he draws from the results of his investigations. I have not the necessary technical knowledge to criticize the methods he employed—no doubt they will be criticized by interested and possibly disinterested persons; but I think the conclusions at which he has arrived from his laboratory findings correspond closely with those formed by most of us from the clinical standpoint. Of the commercial preparations that he tested, I have used only two—namely, dimol and kerol. I have prescribed them in two kinds of cases—one in which bacteriological examination of the stools and serological tests showed that there was a definite intestinal infection, usually with a *Streptococcus pyogenes longus*; the other in which general symptoms, the presence of marked indicanuria, and the faecal examinations pointed to excessive intestinal putrefaction. In no case that I can remember was there any clinical evidence that either of these preparations had any beneficial effect, even after prolonged use.

On the other hand, I think that most bacteriologists would agree that calomel has a definite influence on the bacteriological flora of the intestines, and the same may probably be said of creosote, if given in sufficient dosage, but neither drug is suitable for prolonged administration.

As a dermatologist I meet with three common types of patients with what one may call abnormal intestinal bacterial activity. In Type 1 there is evidence of excessive intestinal fermentation with acid production; these patients are often active, strong, fresh-complexioned persons, but they are seborrhoeic, and subject to the various forms of infection of the skin with the seborrhoeic triad of micro-organisms—the "bottle bacillus," the acne bacillus, and different strains of staphylococci. Their stools are acid and contain excess of the organisms responsible

for intestinal fermentation and acid production. The urine does not contain excess of indican. In them restriction of carbohydrate, particularly of soft, starchy foods and sweets, and the temporary administration of alkalis, lead to a rapid improvement in their symptoms, unless the secondary infection of the skin is of long standing.

In Type 2 there is evidence of excessive intestinal putrefaction; these patients are sallow, pigmented, usually thin, and have marked muscular hypotonus with visceropptosis. They afford, in fact, the classical picture of chronic intestinal toxæmia described by Sir Arbuthnot Lane. Their stools are commonly alkaline, and a large excess of indican may be found, though not necessarily, in their urine. In them it is obvious that treatment must be directed towards changing the intestinal flora from the putrefactive to the fermentative type, and this can only be done, in my experience, by dietetic means, combined with suitable measures for overcoming the intestinal atony and stasis.

Type 3 is a combination of the above two types—that is, there is evidence of both excessive intestinal putrefaction and fermentation. These patients present all the clinical symptoms of Type 2, and are in addition seborrhoeic. The sallow, pigmented person with acne vulgaris is a good illustration of this type, which is the most difficult of the three to treat with success.

It is not too much to say that one can foretell with considerable accuracy the intestinal flora of a person from his general appearance, and, above all, from the state of his skin. The only rational means of changing the flora is by a dietary suitable to the particular case under consideration, and I believe the administration of so-called intestinal antiseptics to be a snare and a delusion.—I am, etc.,

H. W. BARBER.

COMMON SENSE IN RELATION TO DOUBTFUL TUBERCULOSIS.

SIR,—Dr. Weatherhead's criticism (February 27th, p. 401) of Dr. L. G. J. Mackey's paper on "Common sense" (January 30th, p. 211) would no doubt be justified if the latter had advocated treatment at a sanatorium for every suspicious case of early tuberculosis. He expressly does not do this, but on the contrary advises a "restful fresh-air holiday." This being the case, I fail to understand the point of Dr. Weatherhead's letter.

With every word that Dr. Mackey says on this subject I am in absolute and entire agreement, and if the profession as a whole would take this teaching to heart many tragedies would be avoided and a great cause of reproach to our profession be removed. It amazes me again and again to see with what equanimity some doctors will regard haemoptysis in their patients. Very differently would they regard it if it occurred in themselves or in one of their family. Over and over again I see patients with advanced pulmonary tuberculosis in whom the disease has only just been diagnosed or not yet diagnosed, and who give a history of slight haemoptysis two, four, or more years previously which was ignored by their doctor. There exists a perverse and, to me, inexplicable tendency to explain away haemoptysis—to find some totally inadequate cause.

Apart from mitral stenosis and acute affections of the lung, inflammatory or infarction, haemoptysis is practically invariably tuberculosis or something worse; and the doctor's first duty is to institute a complete and thorough investigation, the most important elements of which are sputum examinations, temperature record, and weight record. I have known cases where over a pint of blood has been coughed up, where no treatment was given, and where nothing bad has occurred for twenty years, but the cause was tuberculosis all the same, and the patient was fortunate. Such cases are rare; the common sequel of a neglected haemoptysis is pulmonary tuberculosis so advanced that the prognosis becomes doubtful, grave, or hopeless.—I am, etc.,

F. G. CHANDLER, M.D., F.R.C.P.

London, N.W.1, Feb. 27th.

SIR,—Dr. Weatherhead's courteous criticism of my attitude in regard to a case of haemoptysis unaccompanied by symptoms or physical signs, occurring in a young person, reveals a fundamental difference of opinion between us.

Both he and I believe the probable diagnosis to be that of pulmonary tuberculosis; but while I advocate that the patient should have immediate treatment and careful observation, he advocates careful observation alone.

I admit that a poor man in such circumstances cannot get adequate treatment without being labelled tuberculous, but I regard the drawbacks of such a label a lesser evil than delay in commencing treatment. I consider that the advantages of immediate treatment in the majority of such cases outweigh the disadvantages of treating as tuberculous the small proportion which would have remained in perfect health without any treatment at all.

But if I am wrong in my estimate of the value of early sanatorium treatment, then I admit that I have no right to ask a possibly healthy blood-spitter to incur the social penalties which Dr. Weatherhead so graphically describes.—I am, etc.,

Birmingham, Feb. 28th.

LEONARD MACKAY.

METHODS FOR MEASLES PROPHYLAXIS.

SIR,—In the article in the BRITISH MEDICAL JOURNAL of February 27th, dealing with a recent publication of mine on measles prophylaxis, your reviewer suggests that the methods described are unlikely to inspire much confidence owing to the fact that the protective substances present in the serums cannot be standardized. This difficulty—always a crucial one with serological methods—has to some extent been overcome by a biological method introduced by Professor Débré of Paris, which is based on an old observation of his, that if the serum of a person immune to measles be injected into the subcutaneous tissues of a patient who is in the catarrhal stage of the disease, a local inhibition of the subsequent eruption will appear ("phenomenon of Débré").

If, therefore, several serums be injected, at this stage, in equal quantities, the measure of the inhibition of the eruption in each case will give some indication of the relative content in immune bodies of the various serums employed.

This method, although certainly not ideal, is the best available at present, and is the one which is being employed in France at the present moment. The reaction is not, obviously, comparable with the Schultz-Charlton phenomenon in scarlet fever, and has not the same diagnostic utility, since once the eruption has appeared no blanching can be produced, even by employing considerable doses.—I am, etc.,

London, W.6, Feb. 27th.

W. S. C. COPEMAN.

DYSENTERY IN MESOPOTAMIA.

SIR,—I entirely agree with Dr. Boney's letter in the JOURNAL of February 13th (p. 303). The recent report on the health of the army with reference to the prevalent types of dysentery in Mesopotamia is almost incredible. Like Dr. Boney, I cannot conceive what change can have taken place in the etiology of the disease, so that all cases of dysentery are now amoebic; the bacillary type having apparently disappeared.

In the course of my laboratory work the figures in 1917 to 1920 were, roughly, two cases of bacillary dysentery to every case of amoebic infection. In addition to the group comprising Flexner's and Shiga's bacilli, representing roughly 50 per cent. of all cases of dysentery, there was a type of bacillary dysentery in which one isolated a bacillus morphologically and biochemically resembling Shiga's bacillus, but failing to agglutinate Shiga high titre serum. This non-agglutinable type would, of course, belong to the 23 per cent. of undiagnosed cases mentioned by your correspondent.—I am, etc.,

Rugby, Feb. 28th.

G. F. MITCHELL, M.D.

PHTHISIS A DISAPPEARING DISEASE?

SIR,—It is a curious sign of the degree to which we are all obsessed by the politicians that Dr. C. E. S. Flemming (February 20th, p. 321) should point to phthisis as one of the disappearing diseases and at the same time publish a chart which strongly hints that it has lately obtained a fresh lease of life. If he produces the mean line from 1847 to 1896 onwards he will find that the disease should by now have been practically extinct. He affirms the necessity to decide the causes not less than to record the facts. He should have therefore included the huge drop from 1842 to 1847, and the mean line from 1842 to 1896 would, he then would see, hit the zero point in the year 1923.

If, further, Dr. Flemming had examined the year 1918 in detail, he would have noticed that the Registrar-General points out that the decline in fatality began during, not after, the war, though the fact was obscured by an influenza epidemic in the last quarter.

In any case, taking the abnormal years 1919-23 into calculation, the decline is not nearly half so fast after 1896 as before it. But if, as appears, poverty is the decisive factor in national mortality, then in appraising results phthisis is an increasing disease, inasmuch as 1917 was the last year in which the effects of the pre-war poverty could be traced. And if he examines his own chart he will find a most suspicious resemblance between the curves 1904-13 and 1919-24.—I am, etc.,

Bath, Feb. 22nd.

B. G. BASKETT.

INTRAMUSCULAR INJECTION OF GUAIACOL- IODINE-CAMPHOR OIL IN RHEUMATOID ARTHRITIS.

SIR,—In the issue of the BRITISH MEDICAL JOURNAL of October 10th, 1925, there was published a paper of mine dealing with a method of treating rheumatoid arthritis and periarticular fibrositis—other than specific types of case—by the injection of an oil containing guaiacol, iodine, and camphor, combined.

After much careful testing of various mixtures of this triple oil I find that the combination which gives the most consistently good results, and which has given most satisfaction in its use, is one containing pure guaiacol 10 per cent., iodine as iodipin 10 per cent., and camphor 5 per cent., in sesame oil. A thin, pure, carefully clarified specimen of this oil should be used in the preparation of the triple oil which is to be sterilized and then put up in ampoules of 1 c.cm. each, or, better still, in 20-minim ampoules, so as to allow of sufficient to provide the full 1 c.cm. dose being drawn up into the syringe. The compound is a thin amber-coloured oil, clear and transparent, and smelling strongly of guaiacol; there should be no haziness or deposit of any sort, no matter how long the preparation is stored.

Numerous reports have reached me of satisfactory results having been obtained by using this triple oil. In a few old-standing and chronic cases, where much deformity and rigidity existed, the result so far has been somewhat disappointing. Yet the more extended use of the oil may improve even these if the treatment is persevered in, and care taken to make use of all the supplementary means suggested in the original paper. Massage is not well tolerated as being too painful, and is best used to counter the disuse atrophy of muscles; but where gentle passive movements of joints, gentle stretching, and local radiant heat baths have been utilized regularly after each injection the results have been more satisfactory, the effect of the oil being, very likely, accentuated. In the case of a lady who had had much iodine in various forms, both externally as well as internally, an intolerance of iodine occurred; in her case guaiacol 10 per cent. with camphor 5 per cent. (without the iodine) has been suggested for use.

As to dosage of the combined oil: if a stronger dose is thought to be desirable for any case, it seems to me wiser to repeat the maximal amount of 1 c.cm. more frequently so as to produce a continuous, rather than an explosive, effect. There is, so far as I can see, no

evidence that larger doses at longer intervals will be more effective. It must be borne in mind that guaiacol injected has been known to cause collapse, so that caution must be observed in giving large doses. Using the oil made according to the formula advised, there should be no irritation or pain to speak of apart from the needle prick; even the prick need hardly be felt if the needle is pushed in slowly and deliberately; it is the quick stab which hurts.

I have several times been asked how long a course of treatment should continue. The only reply I can give to that question is: that the treatment should be gone on with steadily so long as benefit can be obtained from its use, and so long as the iodine is being normally excreted. A colleague informs me that delayed improvement occurred in a case of his some weeks after a course of twelve injections had been given. One other matter seems to me to be of great importance: as complete a general detoxication of the patient, without using means which are too drastic, should, if possible, be obtained during the treatment with the triple oil.—I am, etc.,

S. WATSON SMITH, M.D.; M.R.C.P. Edin.

Bournemouth, Feb. 14th.

HAMILTON DRUMMOND MEMORIAL FUND.

SIR,—In your issue for October 24th, 1925 (p. 766), you kindly published a first list of subscribers to the above fund. Since that date further sums have been received or promised from those whose names are appended to this letter, making in all a total of £533 17s. 6d. In addition, a sum of over £286 has been subscribed by past and present officers of the Northumberland Yeomanry.

Doubtless there are still many others who will wish to join in this tribute, and the committee will be glad if they will do so at once.

Individual subscriptions for any amount not exceeding five guineas may be sent to the treasurers (Professor R. P. Ranken Lylo at 11, Osborne Terrace, or Mr. Philip E. Noble at Lloyds Bank, Grey Street), or direct to me at The Hawthorns, Osborne Road, all in Newcastle-upon-Tyne.—I am, etc.,

G. GREY TURNER,
Convenor.

The March issue of the *Edinburgh Medical Journal* is devoted largely to tuberculosis. It contains articles on the virulence of tuberculous viruses, by Drs. W. T. Munro and W. M. Cumming; the surgical treatment of renal tuberculosis, by Mr. Henry Wade; the production of certified milk and early tuberculosis in cows, by Sir Robert Philip and Dr. J. C. Simpson; the light treatment of tuberculosis, by Sir Norman Walker; serology of the tubercle bacillus, by Dr. W. M. Cumming; pulmonary tuberculosis in infancy and childhood, by Dr. L. Findlay; and some statistical aspects of tuberculous meningitis, by Dr. J. L. Halliday.

Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

SUPPLEMENTARY Estimates have been considered in the House of Commons this week, and other business has included a debate on aid to necessitous areas. The Births and Deaths Registration Bill obtained a second reading on February 26th, and will be sent to Standing Committee A, where it will be considered after the Criminal Justice (Increase of Penalties) Bill and the Adoption of Children Bill. The Midwives and Maternity Bill, introduced by Dr. Fremantle, was read a second time on March 1st without discussion, and will also be referred to Standing Committee A.

On March 2nd the Unionist Health and Housing Committee of the House of Commons, with Dr. Fremantle in the chair, conferred with the Minister of Health, who explained the four bills which he hoped to pass into law this session. These were the Local Authorities (Emergency Powers) Bill, to continue the present use of the Metropolitan Common Poor Law Fund; a bill to authorize the removal of guardians who act illegally; a Borough and County Borough Extension Bill, based on the interim report of the Royal Commission on Local Government; and the Smoke Abatement Bill. This last was to be a moderate measure which would not impose heavy burdens on industry or the householder, but might stimulate local authorities to more use of the powers they possessed. It would provide penalties for the emission of smoke of other colours than black, and for the emission of grit.

A meeting of the Parliamentary Medical Committee was summoned for March 3rd to consider the British Medical Association memorandum on the Coroners Bill, and to meet a deputation from the British Medical Association on the subject of the bill promoted by the British Joint Council of Opticians.

On March 2nd, on the motion of the Government, a Select Committee was appointed to consider and inquire into the question of the inspection and supervision of nursing homes, and to report what legislation, if any, was necessary or desirable for that purpose. The committee was composed of Sir Cyril Cobb, Dr. Vernon Davies, Sir C. Forestier-Walker, Colonel Hurst, Sir Richard Luce, Mrs. Philipson, Major Price, Dr. Salter, Miss Wilkinson, and Mr. C. H. Wilson.

MEDICINE AND THE PUBLIC.

About sixty Peers and members of the House of Commons attended a meeting at the House of Commons on February 25th to hear, at the invitation of the Parliamentary Medical Committee, an address by Lord Dawson of Penn on the relations of the medical profession, the General Medical Council, and the public. Dr. F. E. Fremantle, chairman of the Parliamentary Medical Committee, presided. Mr. Norman King, registrar of the General Medical Council, also attended.

In opening the meeting Dr. FREMANTLE recalled that last October members had been asked to attend a meeting at which osteopaths, chiropractors, and others were invited to state the case for special registration. The Medical Committee felt that as the osteopaths had first innings members of the Houses of Commons and Peers would desire to hear the doctors' side of the case. The Medical Committee reserved the right to differ from Lord Dawson, whose pronouncement was not to be taken as representing the medical profession. On one thing medical members of both Houses agreed, and that was in the traditional desire of the profession to protect the public. The public had not recognized that the essential duty of the G.M.C. was not merely to do personal justice, but to protect the public on the lines laid down in the Act of 1858.

Summary of Lord Dawson's Address.

Lord Dawson said the subject on which he proposed to speak had been overlaid with a certain diffuseness and bitterness of spirit. At present there was considerable criticism against the medical profession—he had never known this feeling so strong as now. The profession had no complaint against criticism, but in the course of the recent discussion there had been not a few suggestions that doctors were actuated by selfish class motives. That was not true. They had the ordinary mixed motives of mankind. If they were too good they would not be able to understand human nature, but a selfish policy would be the negation of the doctor's life. True, the medical man had his foibles. The profession did not like secrecy in regard to discoveries, and when a man combined secrecy with gain they claimed the right to cast him out. Moreover, they expected the successful man to undertake a

certain amount of unremunerative work for public service. Doctors, he remarked, were quixotic enough to give the public advice on health which if followed would deprive them of much of their livelihood. The criticisms showed real disquiet and doubt whether all was well, and it was right that the medical profession should try to meet these doubts. He proposed to deal mainly with the relation of the medical profession to unqualified practitioners, a general topic which covered the grievances of Sir Herbert Barker and Dr. Axham. The profession accepted the principles that the good of the public should be the overriding principle, and that the profession should avail itself of knowledge from any quarter if of benefit to the people. They did not contemplate the legal prohibition of unqualified practice, but they were concerned with the question whether it should be recognized by the medical profession and the State.

Aims and Methods of Medical Education.

The crux of the situation was that diagnosis of disease must precede its treatment. The average period of medical studentship was five and a half years, and the primary object of the education was not to push in empirical facts but to teach the man to think. More than half the time was taken up with sciences which had no direct connexion with medicine. Every student had to dissect the human body. That preliminary training was not concerned with medical theories. It was pure knowledge. In the last two and a half or three years of the curriculum they taught the student disease in the wards and laboratories and by *post-mortem* study. Not till nearly the end of that course did they deal with treatment at all, though all the controversies raged round treatment. They could teach their men treatment quite quickly provided they knew disease. It would be criminal not to make a stand on the principle that there should not be any recognition of a man as an independent practitioner until he had been trained in diagnosis. After the finish of the training they put no limitations on medical men. They could become *homoeopaths*, osteopaths, chiropractors, and he had presided at a meeting the other night which was addressed by an osteopath with a medical qualification, who had a fair hearing. Science was the same for all; there could not be two anatomies, two physiologies. "Build," he said, "what theories you like provided you have learnt your job." That was demanded in other professions. If a man said, "I have a special gift. Without training I can build a bridge across that river," his hearers would tell him to qualify as an engineer. They insisted on special training for lawyers. They compelled every sea captain to study navigation before he navigated his ship. Why not insist on equal precautions on the sea of life? Let the osteopaths select their most brilliant students, put them through the medical curriculum, and then put them forth as osteopaths. The medical profession would never give way on the subject of adequate training.

Auxiliaries and Irregulars.

When a proper diagnosis had been made there was room for great latitude in the question of treatment, and he prophesied that treatment would often in the future be delegated to services ancillary to medicine. The medical profession had foreseen this, as shown by the fact that they had recently instituted a system of certificated midwives. He also mentioned the bacteriological assistants, the nurses, masseurs, and the operators of x-ray and light treatment, over all of which the doctor had a co-ordinating control. As far as osteopathy was concerned, if he personally found that an osteopath possessed, as he often did, manipulative skill, he welcomed his aid conscientiously given, provided it had been preceded by medical diagnosis.

It was part of the duty of the medical profession to protect the public from "stunts" and fancies, even if honest. These rose and fell in a never-ceasing stream, and were put forward with astounding light-heartedness. There was deep set in the human mind from the primitive ages a belief in the miraculous in medicine. Everyone was hunting for a short cut. Although he personally was in favour of listening to everything, they had to approach these new cults and fads with proper caution.

Osteopathy.

Osteopathy was only one of the new forms of practice, but it had been so much in the public mind that he dealt specially with it. Manipulative surgery followed bonesetting, in which

Sir Herbert Barker had followed Hutton. Bonesetting, or manipulative surgery, meant gifted fingers, and it was clear that its leading exponents had these. This gift might be of use provided diagnosis preceded its exercise. Human beings were not built in water-tight compartments; many a bad joint was due to disease of the lungs or heart. The manipulative surgeon talked, as the doctor was forbidden to do, about his successes, but he said nothing about his failures. Lord Dawson instanced the case of a youth with undiagnosed painful joints who was beautifully treated by a manipulative surgeon, but became worse because the affection of the joints resulted from gonorrhoea. Another case was that of a patient beautifully treated for paralysis of the legs—but he had a tumour. Diagnosis might thus be delayed, though the thing for which the medical profession was striving was earlier diagnosis.

The average osteopaths about the country did not excel in treatment, yet they were boomed in the press and by M.P.s, who never mentioned Sir Robert Jones, who was the greatest manipulative surgeon in the world. Sir Robert had formed manipulative clinics all over the country. He had more in his little finger than the osteopaths had in their whole bodies.

Lord Dawson turned to the theory underlying osteopathy—that all illness resulted from displacements of the spine or from pressure on the nerves and blood vessels. That was sheer buffoonery. The x rays could show whether there was displacement of the spine, and dissection could show whether there was pressure on nerves and blood vessels. Investigation by these means had shown that in no case was there the displacement or pressure which the osteopaths postulated. There were rival sects to the osteopaths, such as the chiropractors, from whom had sprung the *napropaths*, and if his hearers waited a few months they would get many more sects. He repeated that the crux was diagnosis. Given that, medical men would accept aid from anyone who would give skilled treatment. Osteopaths had the choice of going through the medical course or of giving skilled treatment under medical control.

The General Medical Council.

Turning to the General Medical Council, Lord Dawson said it might vary in composition from time to time. Recent criticism of the personnel might be deserved, but that did not justify criticism of the Council as an institution. He himself disagreed with the G.M.C. in several particulars, but his duty while seeking to secure amendment was to obey. Recent offenders had wilfully broken the law. There were cases in life where a man's defiance of authority for conscience' sake might be justifiable; but he should be very careful to see that his defiance was not associated with material gain. As to the suggested nomination of lay members, he asked his hearers how the nomination of laymen would be accepted if made to the Bar Council, or if outsiders were nominated to the Trades Union Council by the Home Secretary. In conclusion, he emphasized the point that good work in medicine was never theatrical, and that wonder-working and short cuts were always to be distrusted. Whether his hearers agreed with him or not, he asked them to believe that the medical profession was actuated by a desire to serve the public welfare.

DISCUSSION.

Mr. Ropner asked Lord Dawson to explain the relations between a bonesetter and a medical man where the services of the former were invited after diagnosis.

Lord Dawson said there could not be intellectual equality, but in the limited field of treatment there would be courteous comradeship.

Answering Sir E. Hume-Williams, Lord Dawson said they did not propose to make osteopathy without diagnosis illegal. Provided the doctor was satisfied that the osteopath was honest according to his lights and that his work was good, and that the patient wished to be treated, he would agree to such treatment. His opinion was that a doctor doing so would no more be covering than if he was employing an unqualified masseur. "Covering" was when the initiative was taken by an unqualified man who did not understand what he was treating. He would punish any doctor who did that.

Mr. Norman King said Lord Dawson was correct. If the registered medical practitioner was responsible for the treatment and took a patient for it he would not be "covering." But if the doctor, as in the case of Mr. Axham, was employed by the unqualified practitioner, that was "covering."

Mr. Peto said that in a certain case Lord Dawson sent a patient to Mr. Barker, as he then was. In that case Mr. Peto presumed that Mr. Axham was entitled to administer an anaesthetic. Mr. King said "Certainly," as the patient was Lord Dawson's.

Mr. Peto asked why, when Sir H. Barker had offered to demonstrate his methods at any hospital for the benefit of young

MEDICAL NOTES IN PARLIAMENT.

students, the medical profession had refused the offer. Lord Dawson said they deprecated young students being dragged into these questions before the proper time. He would like to see a written document containing the actual words of Sir H. Barker's offer. Some of his colleagues had tried the work of osteopaths, but had often been met with an evasion and an excuse. If any such offer as the reported one by Sir H. Barker had been made a demonstration could easily have been arranged. If Sir H. Barker had followed the medical tradition of doing work of an unremunerative character, or had thrown open his clinic, this demonstration would have been simple. Lord Dawson declared himself astonished that Sir H. Barker had not taken the opportunity to found a clinic to which doctors would come from all the world to see his work.

Mr. Peto said he would obtain from Sir H. Barker the document containing the offer to demonstrate. Sir Martin Conway asked what would happen presuming that his own physician, having diagnosed his case, refused to approve his going to an osteopath, but that he still insisted in going, and in the subsequent treatment a qualified physician administered an anaesthetic. Would that physician be deemed to be "covering"? Lord Dawson said that was a technical question, but the growing complexity of treatment.

Asked about M. Spahlinger, Lord Dawson said that inquirers could not get down to the facts to form an opinion. Medical men were all anxious to know the facts and prepared to take steps to find out.

Lord Knutsford reminded members of the House of Commons that they like to see that no man who was unqualified was allowed to practise medicine.

Lord Balfour of Burleigh said one reason for the public uneasiness was that there was no appeal from the G.M.C. He asked Lord Dawson whether some sort of appeal could not be arranged.

Lord Dawson said he was quite prepared to accept a right of appeal, provided that he knew what the appeal court would be. However, he was convinced that justice was done now.

Dr. Fremantle said the opinion of the highest lawyers was that it was right the profession should be judged by the profession, and that was the intention of Parliament in 1858.

Mr. Neville pointed out that there was an instance where an appeal from a professional court was to an authority not a member of the profession. The appeal from military tribunals was to the Judge Advocate-General, a barrister.

On behalf of those present Mr. Basil Peto thanked Lord Dawson for his address.

Registration of Births and Deaths.

On February 26th Mr. Tinné moved the second reading of the Births and Deaths Registration Bill "to render more complete and effective the safeguards afforded by the law of registration, in relation to disposal of the dead, with a view to eliminating, so far as possible, any element of risk or opportunity for the concealment of crime." He said the promoters of the bill had also had much correspondence on premature burial, and he quoted from the memorandum that "provision is made enabling local authorities to arrange for the medical inspection in certain cases of the body of the deceased person and for regulating certain means of disposal. Stillbirths were required under the bill to be registered as a measure of additional safeguard for the protection of infant life." A Select Committee had reported on the subject of the bill in 1893, and its recommendations were incorporated in the present bill. The bill sought to get over one of the objections to previous ones by eliminating a clause as to the universal medical inspection of bodies before burial. A new clause authorized county councils, in any borough councils, and metropolitan borough councils, in any case where a body had not been seen by a registered medical practitioner since death, to verify the cause of death by the services of such a practitioner, at the request of the coroner.

Mr. Tinné pointed out that the present law did not restrict the disposal of a body except in burial or by cremation. It might be taken out to sea and put overboard without detection if there had been any crime. The bill proposed that in future any birth, whether still or live, would have to be registered, and that the body of no stillborn child should be disposed of without the proper certificate. There had been a good deal of trouble in regard to medical certificates in the past, as, though the registrar could send a particular form of certificate to a doctor who had attended a patient in his last illness, it had not been necessary that the doctor should use that form. He hoped that the bill would get over that difficulty.

Dr. Fremantle seconded. He recalled that the Select Committee of 1893 recommended that "uncertified deaths as a class should cease to exist." The Departmental Committee of 1909 on the Law relating to Coroners found that "the present law of burial and interment affords every opportunity of crime." Cases where death certificates had been carelessly given cropped up every now and then in public and in the courts, and when reported had a serious effect on a large number of people thought it necessary to provide wills that large numbers to be made on their reputed corpses to ensure their death. Speaking as a medical man, he believed the danger of premature burial was exaggerated, but instances did occur where persons were disposed of or steps taken to dispose of

them unwittingly, they being thought to be dead before death had occurred. A county medical officer of health had sent him an extract from a newspaper alleging that at Darlington an infant presumed to be stillborn had been placed in a coffin and taken to the cemetery, where the coffin was opened and the baby found to be still alive; it was seen by a medical man before it subsequently died. Dr. Fremantle recalled that in 1923 a bill had been introduced which was prepared under the auspices of the British Medical Association. A little later a bill had been introduced by Dr. Salter. Then the Federation of Medical men, Services appointed a committee of representative medical men, coroners and undertakers, and a bill resulted which he himself introduced in 1924. Mr. Wheatley, then Minister of Health, privately approved that measure. In 1925 Dr. Fremantle had reintroduced the same bill, but the Minister of Health felt that certain points were impracticable. A conference had followed with officials of the Ministry of Health, and the result was the present bill. The Registrar-General and his officials had endeavoured to improve the certification of deaths, and the figures obtained were of great scientific value, but there was a gap, particularly in cases where, to spare the feelings of the relatives, the medical man gave the terminal result which caused the death instead of assigning it to the primary and original cause. In that way the statistics of syphilis and alcoholism were quite unreliable. It had been suggested that the medical man should give two statements, one of the fact of death and one of the cause, and that the second should be sent confidentially to the Registrar-General for statistical use. But if such a provision had been inserted in the bill the insurance companies would still want to see the more intimate and confidential certificate. Doctors were not fond of filling up forms, and if they gave them two to fill up for one incident they were unlikely to get either form correct. The bill made it essential that the medical man, in giving his one certificate, should give it on the prescribed form which went to the Registrar-General. By improving on the present system and gaining more experience from registrars and medical men they would secure the system of certification which they desired. Dr. Fremantle then explained why the bill did not propose that every death should be verified and a medical certificate given only after a medical man had inspected the body after death. The Minister of Health had demonstrated to him in conversation that in a large number of cases this could not be done. At present in only about 30 per cent. of cases was it certified that the bodies were seen by the medical men after death. When a case had become chronic and the doctor knew it had passed beyond his aid, his visits became fewer. Often a nurse was installed whom he knew Eventually he was notified by letter of the death which he knew was inevitable, and, the cause being known, signed the certificate. To require him to visit the body would give confidence undoubtedly, but doctors were busy men, and if the State insisted on the visit the State would have to pay fees for the doctor's time and travelling expenses. Such expenditure could not be proposed in a private member's bill. In 99 cases out of 100 the medical man did what was intended, and the bill provided that all cases of death would be seen when the local authority thought it necessary. That suggestion appealed to him. He also asked the House to support the clause making the registration of stillbirths essential. In many sad cases there was nothing to prevent an infant born alive from being represented as never having lived at all, and it could be disposed of within the law. That the law could be defeated by those deliberately breaking it would still be possible.

Mr. Arthur Greenwood (who was Parliamentary Secretary to the Ministry of Health in the last Government) said the bill was long overdue and an improvement on earlier editions.

Sir Kingsley Wood (the present Parliamentary Secretary to the Ministry of Health) said that department thought the present safeguards afforded by the registration laws in connexion with burial were not only incomplete but ineffective, from lack of machinery and power to enforce them. The position to-day was the same as in 1893. The standard of the medical profession, however, was higher still to-day than it was then, and the undertakers certainly had a much higher and better disposal of bodies. The bill provided that disposal to all forms of disposal of the registrar's certificate or the coroner's order, and that portions of the document should be filled in and sent back to the registrar in every case, notifying the date and manner of disposal. This was good machinery for preventing a body being buried under an authority which related to another body. The bill put duties upon certain persons to be effect the disposal of a body. These persons would have to be defined more closely in committee. The provision that the doctor would be required to send his certificate of death direct to the registrar was a necessary change from the present practice of handing it to some relative. At present, if a certificate were suppressed the registrar never heard of the death at all. He would obtain improved medical information on the cause of death. He thought that a complete medical inspection of all dead bodies would probably be a costly safeguard against a very small danger, and would be a costly safeguard against a very small danger.

Sir Richard Luce did not think that the bill went far towards carrying out the objects it had in view. Its methods for securing the prevention of crime and the prevention of premature burial seemed to him totally inadequate. No attempt had been made to improve the scientific knowledge of the cause of death. It was quite true that in some cases the medical man did not give a complete account of the cause of death, usually to spare the feelings of the relatives. Though the certificate was to be sent direct to the registrar, it would not be confidential. There should be a provision either in this bill, or in the Coroners Bill already introduced in the House of Lords, that in cases where the medical man doubted the cause of death, or where he believed the death was

due to violence or accident, it should be his duty to inform the coroner, and the coroner, not he, should give the certificate. It was the custom for coroners to find fault with doctors who gave certificates in these cases, but the law definitely laid down that this was their duty. He would not oppose the second reading.

Sir Douglas Newton and Mr. Grottrian declared that the penalties provided in the bill for infringement should be increased. Mr. Dennis Herbert thought the bill required scrutiny by lawyers.

The bill was then read a second time and sent to a Grand Committee.

Answering Colonel Day, before this debate, Mr. Chamberlain said the subject of death certification was already under his consideration with other related matters, but he could not see his way in present circumstances to introduce any legislation. Colonel Day, in his question, suggested amendment of the law to compel the examination of the body before a death certificate was issued by a medical practitioner.

Colonial Medical Service.

Colonel Day asked the Colonial Secretary if he was aware of the manifesto issued by the British Medical Association on the acceptance by doctors of colonial appointments, and whether he would reconsider the new regulations with a view to consultation with the Association.

Mr. Amery said he had seen this announcement, which arose out of regulations recently issued for the East African Medical Service. It had been published before he had had an opportunity of considering the representations which members of the medical staff in East Africa wished to make to him on the effect of these regulations on officers already in the Service. He had now received and considered these representations, and had reached certain decisions on the points raised. He had intimated to the British Medical Association that he was prepared to receive a deputation from it.

Hospitals and Local Authorities.

Mr. Chamberlain, replying on March 1st to Mr. Robinson, who asked the number of hospitals in England and Wales provided and aided, respectively, by local authorities; the total number of beds available; and the number of maternity, tuberculosis, infectious diseases, and other hospitals, said that so far as general hospitals were concerned the information in his department indicated that one large general hospital, with 750 beds, and three relatively small accident hospitals had been provided by local authorities. The total number of beds was not known. Under the Local Authorities (Expenses) Act, 1887, sanctions had been given from time to time to donations and subscriptions by local authorities to voluntary hospitals, but these had generally been for small amounts. Since August, 1925, local authorities had been empowered by Section 64 of the Public Health Act, 1925, to make reasonable subscriptions or donations to voluntary hospitals to the extent of the produce of a penny rate. These payments did not require his sanction, and he was therefore unable to state how many hospitals had been aided in this manner. The information with regard to hospitals of other classes was:

A. Hospitals Provided by Local Authorities.

	No.	Beds.
For tuberculosis	153	10,963
For acute infectious diseases	1,040*	37,700*
Maternity hospitals (not including maternity wards in general hospitals or Poor Law institutions) ..	63	908
Babies' hospitals	12	260

* Round figures. At 52 of these hospitals there were 2,230 beds for the treatment of tuberculosis.

B. Voluntary Hospitals aided by Local Authorities.

General hospitals—	No.	Beds.
(a) Used in connexion with tuberculosis schemes	153	†
(b) Used in connexion with venereal diseases schemes	139	†
(c) Maternity sections used in connexion with maternity and child welfare schemes ..	12	175
Tuberculosis hospitals	127	8,563
Maternity hospitals (not including maternity sections in general hospitals) ..	52	917
Babies' hospitals	12	334

† Available beds used as and when required.

The figures under the above headings were exclusive of accommodation in homes for unmarried mothers and their babies, observation wards in connexion with maternity and child welfare schemes, and convalescent homes.

C. Institutions Provided by Poor Law Authorities.

Institutions wholly for the sick, exclusive of institutions for mental cases ..	No.	Beds.
Mixed institutions (with a total accommodation of some 160,000) ..	64	32,250
.....	530	79,000*

* Beds for the sick.

Vaccination and Small-pox.

On March 1st Mr. Groves asked the Minister of Health whether, in view of the evidence placed before the French Academy of Medicine indicating that vaccination might increase susceptibility to encephalitis, he would consider the advisability of suspending the operation of the Vaccination Acts while the whole question of the danger of increasing susceptibility to

disease in general by vaccination against a single disease was investigated. Sir Kingsley Wood replied in the negative. He added that the investigation of methods to diminish or remove any risks which might result from vaccination was one of the matters referred to the Committee on Vaccination which had recently been appointed. As at present advised, the Minister of Health saw no necessity to consider any interference with the operation of the Vaccination Acts.

Sir Kingsley Wood told Mr. Groves, on March 1st, that the Minister of Health had received the report of the British delegate on the conference of members of the Health Committee of the League of Nations at the Hague, in January, but the suggestions of the conference had not yet been transmitted by the Health Committee. As soon as these suggestions were received they would be referred for consideration to the Committee on Vaccination which was recently appointed.

Sir Kingsley Wood informed Mr. Whiteley that 665 cases of small-pox were notified in the county of Durham during the four weeks ended February 20th. Fewer cases were notified in the week ended February 20th than in any of the previous six weeks, but at present there was no sign of any substantial abatement of the epidemic. Mr. Whiteley asked when the loans requested had been granted in order to provide the equipment and staff to deal effectively with the cases. Sir Kingsley Wood replied that the application from the county council for sanction to a loan was now under consideration. Mr. Whiteley asked whether the Ministry of Health would spread the loan over a longer period than it had previously allowed. Sir Kingsley Wood said he would consider that, but the Ministry only received notification of the epidemic in the county of Durham five or six days before the question was asked, and a representative of the Ministry had immediately been dispatched to the district. Mr. Harris asked whether this epidemic were not the worst England had had for many years, and whether a spread to the neighbouring counties would not be very serious. Sir Kingsley Wood said it would appear that the severity of the disease itself was not so serious, but he asked for notice of any question concerning the danger to neighbouring counties. Commander Williams asked what steps the Ministry of Health was taking to let the local authorities know that a great deal of this epidemic could be checked by increased vaccination. Sir Kingsley Wood said the Ministry had already communicated with the local authorities in the matter, and was constantly urging them to take this precaution.

In reply to Mr. Scrymgeour, Sir Kingsley Wood said 5,365 cases of small-pox were notified in England and Wales during 1925, but this figure was subject to revision. Death was attributed solely to small-pox in three instances, while in six other cases other causes were also entered on the death certificates.

Ophthalmic Benefit.

Sir Kingsley Wood, in answer to Mr. Viant, said that before the commencement of the new schemes of ophthalmic benefit last July, representations from bodies of opticians were made both to the Minister of Health and to the Royal Commission on National Health Insurance. The Minister had not since received any deputation or general observations from them with regard to the administration of the schemes, but was arranging to receive a deputation at an early date. In reply to Mr. Rhys Davies, Sir Kingsley Wood said he was not aware of growing dissatisfaction at the administration of these benefits. The National Health Insurance Commission's report was expected shortly and would no doubt deal with the matter.

Mr. Viant also asked the Minister of Health if he was aware that the proportion of refraction cases referred by some panel practitioners to ophthalmic surgeons was extraordinarily high, while the number so referred by other panel practitioners was exceedingly low; and whether he would issue instructions to such practitioners which would ensure greater uniformity; and further, if he was aware that many cases of refraction, where no ocular disease existed, were being referred to ophthalmic surgeons, thereby seriously depleting the surplus funds of approved societies unnecessarily; and if he would make regulations limiting the cases in which reference to ophthalmic surgeons was permitted. Sir Kingsley Wood said it was no part of the duty of an insurance practitioner to refer applicants for ophthalmic benefit to ophthalmic surgeons, but where the practitioner was of opinion that a patient was in need of ophthalmic treatment or optical appliances he gave him, if desired, a written recommendation to be forwarded to his approved society. It then rested with the society to decide whether the application for ophthalmic benefit was to be granted, and, if so, whether the payment that it would make was to cover the cost of examination or treatment by an ophthalmic surgeon. He knew of no good reason for seeking to limit the discretion of societies in the manner suggested, and, in any event, had at present no power to make regulations for such a purpose. It was better, at any rate for the present, to keep the matter in the discretion of the approved societies. Mr. Rhys Davies suggested that the approved societies had no power to act in the way Sir Kingsley Wood suggested. Sir Kingsley Wood said the Ministry was advised that the approved societies could themselves come to a determination in the matter, and they were constantly doing so. Mr. Compton asked whether Sir Kingsley Wood was aware that the State auditors refused to sanction payment in these cases unless the medical certificate had been given in the first place and that the approved societies had no discretion in the matter. Dr. Vernon Davies asked whether the House was to understand that the approved societies decided that the ophthalmic surgeon should be consulted, or did the doctor in charge of the case do this? Sir Kingsley Wood thought this was generally done by consultation between the approved society and the doctor on the panel.

Encephalitis Lethargica.

Mr. Neville Chamberlain (Minister of Health) informed Mr. Compton, on March 1st, that at present there was not sufficient information available to enable an estimate to be given of the percentage of recoveries from juvenile encephalitis which had suffered mental or moral injury from that disease.

On March 1st Mr. Ammon asked the Parliamentary Secretary of the Ministry of Health what investigations were being carried out by his department with reference to mental cases, and particularly cases of encephalitis lethargica. The question was put during a Supplementary Estimate for £23,860 for salaries and expenses of the Board of Control (Lunacy and Mental Deficiency), England, and grants in respect of the maintenance of certain ex-service mental patients.

Sir Kingsley Wood, in reply, said that the inquiries taking place were not a general inquiry into the lunacy laws of the country. A special committee was sitting, and it was hoped to have its report at an early date. The technical committee appointed jointly by the Board of Control and the Board of Education was to inquire into the incidence of mental deficiency throughout the country, as there was a lack of knowledge on the number of cases and what arrangements should be made for dealing with them. He hoped that the investigation might end by March, 1927. It was being conducted by one of the principal officers of the Board of Control, but it might possibly continue for another year, as they had come to the conclusion that it was important to get accurate information on the real extent of the problem. It was only in the last two or three years that the disastrous mental after-effects of encephalitis lethargica had come to light. It was true that it was a notifiable infectious disease, and local public authorities had power to treat cases in their isolation hospitals, but there was no duty on the authorities to provide for persons suffering from the mental after-effects, and, outside London, he regretted to say, there was no hospital provision. A certain number of cases were certified and sent to mental hospitals or mental deficiency institutions. In some of the larger areas, in London and Lancashire, these cases were concentrated in one mental deficiency institution in each area. It was decided last year to establish a hospital, limited to 100 beds, in London for cases under 15 years of age, under the Metropolitan Asylums Board. Children of either sex were being admitted. This was an experiment, by which they hoped to be able to gain much more knowledge of the unfortunate after-effects of this disease than they possessed at present. They felt that their present powers in dealing with this disease were insufficient. The definition of mental deficiency was very limited. It really prevented their making the necessary arrangements for detention.

Mr. Ammon asked if anything was being done in the case of adolescents, where the real trouble came on.

Sir Kingsley Wood replied that although they said children would be admitted under 15, they did not strictly adhere to that particular age. In some cases people were admitted at a much older age. So far as the Board of Control was concerned, it had come to the conclusion that in a very large number of these cases persons who were proceeded against should not certainly be treated as criminals, and it wanted to make proper provision for them. The Minister of Health had now under consideration what further steps should be taken. Mr. Ammon had raised a very important question, which demanded, and was receiving, the attention of a large number of people who were interested, not only in mental deficiency, but in the welfare of a number of young people who were, unfortunately, suffering, and were occasionally brought before the courts of this country. The Ministry of Health had made provision, and they hoped, if further powers were given to them, that they would be able to do something still more in a matter which certainly required attention.

The vote was carried.

On the same day Mr. Ammon asked the Minister of Health whether the Government was inclined to view favourably the offer received from Dr. Damoglou to place at the disposal of the Ministry a method of treatment of cases of encephalitis lethargica. Sir Kingsley Wood replied that the answer was in the negative.

Industrial Fatigue.

Answering Mr. McLean, Mr. R. McNeill, Secretary of the Treasury, said that facilities had been given to the Industrial Fatigue Research Board in some Government departments for investigating special problems arising in particular kinds of manipulative work. An example was telegraphist's cramp. He was unaware of any proposal for a widespread application of tests by medical practitioners among the female employees in all Government offices. The tests of women at the Govan Employment Exchange, made for the Industrial Fatigue Research Board, were not medical examinations. They were simple external measurements made by two women assistants. The tests had not been applied to any officers at the Govan Employment Exchange. A number of women officers at neighbouring exchanges were allowed to undertake the tests at their own suggestion. The Industrial Fatigue Research Board asked, in May, 1925, for facilities to examine women signing at employment exchanges, and preliminary arrangements were completed in November. Consent was given to this scientific inquiry that knowledge might be gained of conditions affecting women's employment. The tests were only sanctioned for, and had been applied only in, the case of volunteers.

In reply to Dr. Fremantle, Sir Kingsley Wood said the Minister of Health was anxious to facilitate the provision of housing accommodation for the employees of new undertakings, but did not think that it would be practicable to introduce legislation making it compulsory for employers to produce such accommoda-

tion. A number of firms had already provided for the housing of their employees.

Colonel Gibbs, answering for the Minister of Health, told Mr. McLean that the investigations of the Industrial Fatigue Research Board did not involve medical examinations, but were concerned with special problems arising in manipulative work. The investigations were made to gain knowledge of a kind likely to improve the conditions or environment of employment, and were not restricted to any particular class of worker. No question of powers arose, as the subjects of test were always volunteers.

The Milk Supply.

In an answer to Dr. Fremantle, Sir Kingsley Wood said the numbers of producers' licences for certified and Grade A (tuberculin tested) milk in operation in England and Wales were 96 and 97 respectively. The number of such licences for Grade A milk on March 31st, 1925, the latest date for which figures were available, was 110. In the herds producing the first two grades of milk were approximately 3,500 and 3,800 cows respectively. The cows in Grade A herds might be roughly estimated at 2,000 to 2,500. Mr. March asked whether the Ministry of Health was discouraging the use of Grade A milk in any way. Sir Kingsley Wood said he had no knowledge of that. In a further reply to Dr. Fremantle, Sir Kingsley Wood said licences for the sale of pasteurized milk were issued by local authorities. March 31st, 1925, was the latest date for which returns were available. These gave the number of pasteurizing establishments as 62, and of other premises licensed to distribute as 370. He had no complete information on the quantity of milk now sold in England and Wales as pasteurized, but on a rough estimate it might be taken to be between 15,000,000 and 20,000,000 gallons per annum. He could not say without notice how often the premises of these firms were inspected by representatives of the Ministry of Health.

Dr. Fremantle asked the Minister of Health if he had evidence that bovine tuberculosis was communicable to man by the consumption of tuberculous milk. Sir Kingsley Wood said the Minister had such evidence. He was advised that the positive conclusions of the Royal Commission on Tuberculosis concerning this subject had been confirmed by the subsequent work of many investigators at home and abroad. Mr. Erskine asked whether the moral to be drawn was not that people should drink orange juice and not milk. Sir Kingsley Wood said he thought the answer contained its own moral.

Insurance Practitioners' Remuneration.—Answering Commander Kenworthy, Sir Kingsley Wood said that sums withheld from insurance practitioners under the powers contained in the National Health Insurance (Medical Benefit) Regulations were not returned to the Central Pool for distribution among practitioners, but were carried to a special fund from which, under Article 21 (2) of the same Regulations, payments were made to Insurance Committees towards meeting exceptional expenses incurred by them in administration of medical benefit.

A Unified Medical Service.—During the debate on the Air Estimates, on February 25th, Major Attlee said these Estimates provided £209,000 for the medical service. In the Army Estimates he found £2,500,000 for the Army Medical Service, and more was provided for the medical service in the navy. They required one medical service for the three and one united hospital service for the three. Colonel Spender-Clay said he could not see why there should be three departments for dealing with medical services. All these services could, even without a Ministry of Defence, be correlated, and a very large sum of money might be saved. Sir Samuel Hoare said he would convey to the Prime Minister the arguments used by Colonel Spender-Clay on the question of a Ministry of Defence, and would give the fact that they had been supported by members in every quarter of the House. It was obvious from the course of the debate that there was a growing feeling in the House for much closer co-operation between the three services than at present existed.

Miner's Nystagmus.—Mr. Spencer asked whether nystagmus was on the increase among coal miners. Colonel Lane-Fox said the incidence of miner's nystagmus was still very heavy, but the total number of cases in 1924 was slightly less than in 1923; the number of new cases declined both in 1923 and 1924, and he hoped it would continue to do so. Mr. Spencer asked whether the Government intended to give effect to the recommendation of the Medical Research Council with regard to a higher standard of illumination by making the provision of such a standard compulsory. Colonel Lane-Fox said he hoped to be able before long to fix a higher candle-power standard for flame safety-lamps. For electric safety-lamps the present standard of candle-power was much higher than the standard for flame lamps, and he was advised that it was not yet practicable to raise this.

Health of Kenya.—On March 1st Mr. Amery, answering Mr. Scurr, who asked if the Governor of Kenya had taken any action with regard to the petition from the Kikuyu Central Association asking for certain reforms in health administration, said that he had no information, but he would inquire of the Governor.

Notes in Brief.

The Admiralty explains that the removal of salt pork from navy rations is a result of the increased facilities for the issue of fresh and frozen meat. When a substitute is necessary tinned meats are preferred.

The Minister of Health cannot say when the bill dealing with slums in towns and insanitary dwellings in country areas will be introduced.

The committee on the pay of the Royal Army Medical Corps has not reported.

Obituary.

A. R. CUSHNY, LL.D., M.A., M.D., F.R.S.,

Professor of Materia Medica and Pharmacology,
University of Edinburgh.

THE sudden death of Professor A. R. Cushny at his home in Edinburgh on February 25th came as a particularly severe shock to his friends because it was quite unexpected. Professor Cushny had been in London two days before at an important conference, and had then appeared to be in his usual excellent health. He was only 60 years of age, and was of unusually fine physique, and all his friends confidently anticipated for him many more years of active work.

Arthur Robertson Cushny was the son of the late Rev. John Cushny of Speymouth, Morayshire, and was educated at Aberdeen University, where he graduated M.A. in 1886 and M.B., C.M. in 1889, when he was appointed Thompson Fellow. After proceeding M.D. in 1892 he went to Germany, and for a year was assistant to Schmiedeberg in Strasbourg. In 1893 he was elected to the chair of pharmacology at the University of Michigan, and he held this post till 1905, when he came to London. While at Michigan he commenced his studies of the action of drugs upon the heart, and also brought out the first edition of his well known textbook. In 1905 he was appointed professor of pharmacology at University College, London, a post which he held until 1918, when he was elected to the chair of materia medica and pharmacology at Edinburgh University, the position he was holding at the time of his death. He was elected a Fellow of the Royal Society in 1907, and served on the council of the society 1916-18. He was a member of various important public bodies, including the Royal Commission on Whisky, the Chemical Warfare Committee, and the Central Control Board (Liquor Traffic).

Professor Cushny's name is particularly associated with his work on the action of digitalis. It was during his time at Michigan that he worked out the mode of action of this drug upon the mammalian heart, and later in London, in collaboration with his friend the late Sir James Mackenzie, he applied the knowledge he had obtained from animal experiments to the treatment of heart disease. He was the first to suggest that certain clinical irregularities of the heart might be due to a disorder of function comparable to the condition of auricular fibrillation, which had long been recognized in laboratory experiments. This suggestion, which soon was proved to be correct, was an extremely valuable one and assisted greatly in the development of our modern knowledge regarding the functional disorders of the heart. Professor Cushny's last contribution to the pharmacology of the heart was his monograph on *Digitalis and its Allies* (1925), a work in which he gave a masterly summary of a vast and confused literature. Professor Cushny also did much

to advance our knowledge regarding the functions of the kidney. He published many papers on the secretion of urine, and in 1917 published a monograph on this subject, in which he not only summarized the existing knowledge, but also advanced a new theory of kidney secretion, based on the idea that the kidney discriminates between threshold and non-threshold substances. This theory provided the first coherent account of kidney secretion that accords with our modern knowledge of physiology and of physical chemistry. A third line of important fundamental research was his investigation of the manner in which pharmacological action is modified by the optical activity of alkaloids. This formed the subject of the Dohme lectures which he delivered in Baltimore last year.

This short account of Professor Cushny's researches does not, however, give any adequate indication of the services he rendered as a pioneer in establishing the science of pharmacology in this country. Pharmacology originated in Germany, and the replacement of the old *materia medica* by the science of the mode of action of drugs has been a slow process in this country; but Cushny did more than any other person to bring about this change. His textbook, *Pharmacology and Therapeutics, or the Action of Drugs*, which is now in its eighth edition, is recognized as the most trustworthy guide to the subject. His wide knowledge and exceptional powers of judgement made him one of that select number of persons who can write a great textbook. The first edition of this book was a pioneer piece of work, for it was the first general textbook of pharmacology to be published, and it had an enormous influence in moulding the development of pharmacology in the English-speaking world. Cushny treated the mode of action of drugs as an exact science, and his book contains statements only

of those facts that have been established by carefully controlled observations on animals or man. Naturally his attitude appeared to some to be unduly sceptical, for he had no hesitation in rejecting cherished traditions as unproven when they lacked definite objective evidence for their support. Now, however, it is generally recognized that this is the only manner by which a science can be built upon secure foundations.

At the Annual Meeting of the British Medical Association in 1910 he was President of the Section of Pharmacology and Therapeutics; for some years he was a valued member of the Scientific Grants Committee of the Association, and in 1906 was a member of the Proprietary Drugs Committee.

Apart from his activities in advancing the knowledge of pharmacology, Professor Cushny had an extensive knowledge of the history of drugs, and in particular was an authority on the life of Withering, the discoverer of digitalis. Mr. Walter Spencer informs us that only last week Professor Cushny had agreed to annotate for the Royal Society of Medicine the collection of Withering's letters bequeathed to the society by Sir William Osler.

Professor Cushny has for long been the doyen and the leader of the pharmacologists in this country, and his

untimely death is an irreparable loss to this science, which he did so much to establish on a sound basis. He leaves a widow and one daughter, and to them we proffer the condolences of the medical profession in their bereavement.

APPRECIATIONS.

Sir Edward Sharpey-Schafer, F.R.S.

The death of Professor Cushny is a severe blow to the University of Edinburgh. When he was appointed in 1918 he succeeded to a chair in which for many years the opportunities for research had been allowed to lapse to such an extent that it was difficult to carry out pharmacological investigations at all, both by reason of lack or antiquity of equipment and the absence of a directing spirit. For his distinguished predecessor, Sir Thomas Fraser, had little time in the intervals of his hospital and private practice to devote to research, and during his latter years was seriously handicapped by frequent attacks of illness and by having suffered an intracapsular fracture of the neck of the femur which greatly restricted his activities. By a rearrangement of duties, and the establishment of a chair of therapeutics, of which Dr. Jonathan Meakins was the first occupant, Professor Cushny was relieved of the clinical work which had taken up so much of his predecessor's time and energy, and was enabled entirely to reorganize the department of materia medica in the university. Under his auspices the laboratories were thoroughly equipped for the most modern methods of investigating the properties of drugs, and workers who before had been conspicuous by their absence were freely attracted to the department, which has become one of the most active in the university. This is not a place to speak of his scientific attainments, nor of the importance of the work which he has produced—these matters are dealt with elsewhere. But to say that it will be difficult to fill the place of Professor Cushny, both in the branch of science which he made his own and in the university to which he has been attached during the last seven or eight years, is a simple statement of fact. Possessing, as he did, a wide knowledge of the subject with which he had to deal, he combined with this abundance of common sense and an unusual strength of character. By these qualities he endeared himself both to his students and colleagues, who will for many a long day miss his wise counsels and his genial personality.

Ave atque vale!

Dr. H. H. Dalc, F.R.S.

The death of A. R. Cushny has fallen as a sudden blow on his colleagues and friends in medical science. On Monday and Tuesday, February 22nd and 23rd, he was in London, and all who came into touch with him had remarked on his mental vigour and good spirits. I had a long talk with him on the Monday evening, when he spoke with quiet optimism of plans for a well earned leisure, after another five years of the work which he loved and enjoyed. From this buoyant mood, and the joy of his return home on the 24th, he was suddenly smitten into unconsciousness by a rapidly fatal cerebral haemorrhage. For himself no way of leaving life could have been happier; but we are left to wonder how his place can be filled.

For Cushny held a place in the medical science of this country which was, in some ways, unique. He had passed early from Aberdeen to Berne and Strasbourg, had worked with the veteran Schmiedeberg, had brought great distinction to a chair of pharmacology in the United States, and had written the first great systematic textbook of pharmacology. He was at home in several countries, and known and respected by every pharmacologist in the world. Yet, when he returned to this country in 1905, with wisdom ripened by an unrivalled experience, he was, and to the end remained, still young in his sympathies and interests, and typically British in the caution and solidity of his character. He was a quiet, undemonstrative man, with a large and generous heart, and his juniors in age and experience soon found that he was tolerant of ideas and of enthusiasm, and warm in his encouragement of good work. He did not easily acquire or relinquish a conviction; but that made his agreement and approval only the more worth winning. He was a wise, big brother to us

all. The sympathy of the many who knew and loved him will go out to his widow and daughter in this tragically sudden end to a family life of unusually perfect sympathy and happiness.

Professor E. H. Starling, F.R.S.

When, in 1905, Cushny was persuaded to accept the chair of pharmacology at University College, London, he had already, by his work at Ann Arbor, Michigan, achieved the leading position in his science. It is largely due to the influence of his teaching that pharmacology has made, in recent years, such great advances in the United States, where his pupils have carried on his work. But at University College he was undertaking the creation of a department out of nothing. Previous to his appointment materia medica and therapeutics were taught by a part-time lecturer, as was the custom in other medical schools. The remuneration was meagre, and the "department" consisted simply of one ill lit and badly furnished room. Nothing daunted, however, by these material disadvantages, Cushny set himself to the building up of a school in London with the calm optimism and the unflinching equanimity which always characterized him in anything he undertook. His sane judgement of men and things made him at once a valued colleague—both in the college and in the laboratory; and there is no doubt that he fully appreciated the society into which he had fallen and the regard in which he was held by its members. When at last, through a generous gift of Mr. Carnegie, it became possible to provide Cushny with a laboratory adequate to his work, we hoped that we had secured his continued and permanent help in building up the school of our ambitions. But to an Aberdeen man the old reputation of a professorship at Edinburgh University was too strong to be resisted, and the succession to the chair of Fraser seemed a fitting crown to his life's work. During these Edinburgh years Cushny has been at his best, and his activities in research as great as during any other period of his life. His masterly work on digitalis and his monograph on the secretion of urine—the second edition of which he had just completed and seen through the press—represent the summary of the two lines of work to which he had chiefly devoted his attention throughout his scientific career. Our modern views on the action of digitalis and the "modern theory" of renal secretion we owe to Cushny. Although his monograph is devoted to a vindication of the "modern theory," we feel that in this, as in all Cushny's work, there is no slavish adherence to a verbal formula. Cushny was of opinion that a theory, if well substantiated to start with, should be tried until it broke, and not be abandoned at the first experimental result which seemed at variance with its teaching. But this meant for him the continual devising of fresh tests for the theory, and thereby the acquisition of new facts and the extension of our knowledge of the subject. To pharmacology, physiology, and medicine Cushny's death is thus a severe loss and one that to his friends is irreparable.

Dr. W. E. Dixon, F.R.S.

Professor Cushny succeeded Sir Thomas Fraser in the University of Edinburgh towards the end of the war, and at once embarked on the task of reorganizing the work in the department of pharmacology and remodelling the teaching. At this time he was the outstanding figure in British pharmacology, a man who had throughout life devoted himself whole-heartedly to the one subject. His textbook, published in 1899 and modelled on that of his master, Schmiedeberg, was the first of its kind published in English, and may be regarded as the model on which subsequent books on the subject have been made. In Edinburgh he collected round him able young assistants in whom, by precept and example, he instilled a new spirit into pharmacology, inspiring them with the search for truth. He was a severe but just critic, and could not tolerate slackness. I remember his sage words to an assistant who wished to do some outside work; he told him that he had better not follow pharmacology if he regarded wealth as the criterion of success. Cushny was a keen investigator and always seemed to me to see a little further than others; he was often right when others were wrong;

either because he knew more or because he was better able to balance his facts. Cushny's work in pharmacology was mainly devoted to investigating the mode of action of well known drugs, rather than by adding to our materia medica. Shortly before his death he told me that when in Michigan he had discovered the condition of auricular fibrillation in animals; he had thought it a condition likely to occur in patients and had asked his clinical friends to search for it. Cushny was careful, frugal in his habits, and lacking in all forms of ostentation; he never shirked his duties or tried to save himself. In Edinburgh he gave practically the whole of the lectures himself, leaving his assistants free for research. He had a quiet, persuasive manner, a genial nature, and a kindly sympathy which attracted to him those needing advice or help in trouble, and only his intimates can appreciate how cheerfully he gave his time and thought in the interests of his assistants and pupils. The world is poorer by his death, but his memory and example remain to inspire us with a courage in our own work and sympathy for that of others.

Professor A. J. Clark.

The untimely, and unexpected death of Professor Cushny is a great loss to his friends and to the medical sciences, but this loss is felt particularly severely by those who, like myself, were not only his friends but also had been pupils under him. A considerable proportion of the holders of chairs of pharmacology in England and the Dominions have been, like myself, assistants to Cushny. All of us, his past pupils, would, I think, mention as his outstanding characteristic the power of shrewd and well balanced judgement, and we have all been indebted to him on innumerable occasions for help and advice on matters scientific and personal. He had a remarkable power of interesting and encouraging young scientists in useful lines of research, and his kindness and patience were inexhaustible.

THE RIGHT HON. MICHAEL FRANCIS COX,
M.D., F.R.C.P.I.,

Late Chairman of Convocation of the National University of Ireland.

THE death of Dr. Michael Francis Cox, after a prolonged illness, removes from the ranks of the medical profession in Dublin one of its leading practitioners. Born at Kilmore, co. Roscommon, in the year 1852, he was educated at St. Mel's College, Longford, the Catholic University, Dublin, and London University. In 1875 he obtained the licentiate, and in 1892 became a Fellow of the Royal College of Physicians of Ireland, and in 1895 the Royal University of Ireland conferred on him the honorary degree of M.D. After completing his medical training Dr. Cox took up first medical teaching, and then commenced private practice; at an early age he rose to a position of eminence in his profession. He had been President of the Royal College of Physicians of Ireland, and during the Lord Lieutenantcy of Lord Aberdeen he was made a member of the Privy Council. Dr. Cox was senior physician to St. Vincent's Hospital, Dublin; consulting physician to the Children's Hospital, Temple Street, to the Linden Convalescent Home, and to Our Lady's Hospice. In the various positions which he held he contributed to the full the resources of his medical skill and experience, and did much to uphold the dignity and traditions of the Irish medical profession, by whose members he was held in the highest esteem. On the occasion of his election as President of the Royal College of Physicians of Ireland in 1922 he was presented with a beautiful replica of the Ardagh cup by his colleagues in St. Vincent's Hospital.

He was an honorary LL.D. of the National University of Ireland, a member of the Royal Irish Academy, a Fellow of the Royal Academy of Medicine in Ireland; Fellow and vice-president of the Royal Society of Antiquaries, Ireland; and a member of the senate of the National University. Dr. Cox had been examiner in medical jurisprudence and materia medica in the Royal University of Ireland, and demonstrator in anatomy of the Catholic University Medical School, Dublin. In 1923 Dr. Cox contracted a serious illness, from which he never wholly rallied from that time up to his death. He was keenly interested in science

and literature, and was the author of *The Country and Kindred of Oliver Goldsmith* and *Notes on the History of the Irish Horse*. In years gone by his lectures on historical and archaeological subjects in several halls, notably that of the National Literary Society, aroused great interest. There were few men more learned in Irish folklore, more particularly that which referred to his native west. His health finally gave way last year, when he definitely retired from active participation in public affairs. On November 11th Dr. Cox resigned the position of chairman of convocation of the National University of Ireland, which he had held from its inception; the occasion was marked by signal expressions of appreciation and affection.

In opening the new dispensary at St. Vincent's Hospital, Dublin, Professor J. S. McArdle, surgeon to the hospital, paid the following tribute to the work of the late Dr. Michael Cox. Having referred to Marsh, O'Farrell, and O'Leary, Surgeon McArdle said: "One other man is unfortunately unable to be with us to enjoy the vision of his hospital's progress. Through weary and often very trying times he was a wonderful counsellor, while in his medical work he was indefatigable; outside his professional effort he was the greatest example of thoughtfulness for the poor that has appeared in my long experience. So persistently kind, so constantly mindful of the trials and troubles of others, his mind must have been attuned by other than earthly influences."

JOHN B. STORY, M.B., M.Ch., F.R.C.S.I.,

Past President of the Royal College of Surgeons in Ireland and of the Ophthalmological Society of the United Kingdom.

We much regret to record the death of Mr. John Benjamin Story, who died at Malahide after a distinguished professional career. He was the son of the late Rev. W. Story of Tyrone, and received his education at Winchester, Dublin, Zürich, and Vienna. He graduated M.B., B.Ch. Dublin in 1876, proceeded M.Ch. in 1888, and obtained the F.R.C.S.I. in the same year. Although he devoted himself to ophthalmic surgery he took a considerable interest in public life, and was High Sheriff of Tyrone in 1911.

Mr. Story held the office of President of the Royal College of Surgeons in Ireland from 1918 to 1920, and during the same period he was also president of the Ophthalmological Society of the United Kingdom, of which he was an original member. He was professor of ophthalmic surgery to the Royal College of Surgeons in Ireland, president and honorary consulting surgeon to the Royal Victoria Eye and Ear Hospital, and president of the Irish Medical Association in 1913. He held the appointment of honorary surgeon oculist to the King in Ireland, and to the Earl of Cadogan and Earl Dudley during their tenure of office as Lord Lieutenant of Ireland. His other appointments included those of ophthalmic surgeon to the Adelaide, Mercer's, Monkstown, and the Dublin Castle Red Cross Hospitals; he was also oculist to the Claremont Institute and St. Joseph's Asylum. Mr. Story published numerous papers on ophthalmic operations and disease. He was the author of "Ocular lesions in variola, rubeola morbilli, scarlatina, erysipelas, and diphtheritis," in *Norris and Oliver's System of Diseases of the Eye* published in 1900, which we reviewed in the *JOURNAL* (1900, vol. i, p. 847). He contributed articles on tuberculosis of the conjunctiva, strabismus, and glaucoma to the *Transactions of the Royal Academy of Medicine in Ireland* and the *Ophthalmic Review*.

He married in 1892 a daughter of the late Rev. J. W. Hollowell, and leaves two daughters.

WILLIAM CHARLES SULLIVAN, M.D.,

Medical Superintendent, Broadmoor Criminal Lunatic Asylum.

We much regret to report the death of Dr. William Charles Sullivan at Bournemouth, on February 26th, in his 58th year. He was the youngest son of the late Dr. W. K. Sullivan, President of Queen's College, Cork, and was educated in Cork, Dublin, and Paris. He graduated M.B., B.Ch., B.A.O. at the Royal University of Ireland in 1891, and proceeded M.D. in 1896; he won the Stewart scholarship in mental diseases in 1895. The early years of his

professional life were spent in the prison medical service, and he held in succession the posts of deputy medical officer of the prisons at Liverpool, Parkhurst, Holloway, and Pentonville. He was next appointed medical superintendent of the State Criminal Lunatic Asylum at Rampton. In 1910 he succeeded the late Sir Richard Brayn as medical superintendent of Broadmoor Criminal Lunatic Asylum, and held that responsible post until his death.

Dr. Sullivan had for many years taken a profound interest in the subject of alcoholism, on which he had published an excellent book in 1896. His opinions were well balanced and persuasively expressed, and he was much respected as an authority in this field. His position was recognized by appointment to the post of scientific adviser to the Central Control Board for the Liquor Traffic which was set up in 1915, and he continued to hold that post until the dissolution of the Board in 1919. Besides these varied duties, he held the post of lecturer in criminology and forensic psychiatry at the Maudsley Hospital, and published numerous articles on psychological subjects. His last book, *Crime and Insanity*, which we reviewed on June 28th, 1924, dealt with the nature and extent of the influence of psycho-pathological conditions on the causation of criminal acts. It was generally considered a most valuable and timely contribution to criminology—an authoritative and convincing work, its conclusions being preceded by closely reasoned discussions.

Dr. Sullivan married Miss Mary Fitzpatrick, the writer of Irish stories, and had one son.

HUGH JONES ROBERTS, M.D.,

Late Chairman, North Carnarvon and Anglesey Division.

We much regret to record the death of Colonel Hugh Jones Roberts on February 18th, in his 64th year. He was the eldest son of the late Dr. Evan Roberts, and received his medical education at Guy's Hospital. He obtained the diplomas M.R.C.S.Eng. and L.S.A. in 1885; graduated M.D.Durh. in 1907, and passed the examination for F.R.C.S.Edin. in 1911. Colonel Roberts succeeded to the practice of his father, which he carried on in conjunction with his brother, Dr. E. Shelton Roberts. He was a pioneer of the Volunteer movement in the Nantlle Vale district, and for several years commanded the 6th Volunteer Battalion of the Royal Welch Fusiliers. He held the Volunteer Long Service Decoration, and served on the Carnarvonshire Territorial Association. During the war he was in command of the military hospitals at Preston and Eaton Hall, and at the end of the war remained in charge of the Ministry of Pensions Hospital at Bangor until it was closed. Colonel Jones Roberts was an honorary associate of the Order of St. John of Jerusalem in England, a member of the Court of Governors of University College, North Wales, and an examiner and honorary life member of the St. John Ambulance Association. For many years he had been a keen member of the British Medical Association. He was honorary secretary of the North Wales Branch from 1898 to 1914; in 1904 he was a representative, and in 1906 chairman of the North Carnarvon and Anglesey Division. He was a member of the Central Council from 1905-06 to 1911-12, and at the Liverpool Annual Meeting in 1912 was vice-president of the Section of Pharmacology and Therapeutics.

A colleague writes: The British Medical Association loses a loyal worker and one who took its proceedings most seriously. He was a model of decorum, and was always "regimental." A quiet dignity was apparent in all his work, and he brought it into play in conducting any Division or Branch meeting at which he was present. He had been in failing health for some years. He took a keen interest in old Welsh literature, and would quote old authors and anecdotes with a charm and smile that was very fascinating. He fathered the idea of having an Association Annual Meeting at Bangor when the new college was being built. The Branch and Divisions took an interest in the matter after the completion of the buildings, but it was found to be impracticable, and he was very disappointed. He was a loyal colleague, and the profession in North Wales will greatly miss him.

J. R. P.

WALKER OVEREND, M.A., M.D.,

Honorary Radiologist, Buchanan Hospital, Hastings, and late X-Ray Assistant, St. Bartholomew's Hospital.

We regret to record the death, on February 10th, of heart failure, of Dr. Walker Overend, at his residence in St. Leonards. Dr. Overend was born in 1858 at Keighley, Yorkshire, and was educated at Skipton Grammar School. In 1874 he was awarded the Queen's scholarship at the Royal School of Mines, and studied under Huxley. Four years later he obtained the B.Sc.Lond., with honours in zoology, and won a university exhibition. In 1882 he obtained the Brackenbury scholarship at Balliol College, Oxford, and in 1886 he secured a first class in the honours school of physiology. He won the Radcliffe Travelling Fellowship in 1887, and studied in Heidelberg and Strasbourg; in the latter town he investigated the effects of veratrin and curare in striped muscle, publishing his results in Schmiedeberg's *Archiv* for 1889. On his return from Strasbourg he held the post of deputy lecturer on physiology at St. George's Hospital for a year. In 1892 he obtained the diploma L.S.A., and graduated M.B., B.Ch.Oxf. in 1893. He then joined a friend in practice at Edmonton, and was elected in 1895 physician to the Prince of Wales's Hospital, Tottenham. He proceeded M.D.Oxf. in the same year, and about this time he published several papers dealing mainly with the heart and lungs. Defective health compelled him to leave Edmonton in 1899, and he settled at Clacton-on-Sea, where he remained until 1912.

His interest was early attracted to the medical possibilities of x rays, and he possessed an x-ray apparatus as early as 1902. He decided to retire from general practice in 1912 and devote himself to the new science of medical radiology; accordingly in the following year he became chief assistant under the late Dr. Hugh Walsham in the x-ray department of St. Bartholomew's Hospital. About the same time he commenced practice as a radiologist at St. Leonards, and was shortly afterwards elected radiologist to the Royal East Sussex and Buchanan Hospitals, Hastings. During the war he acted as radiologist to the Victoria Hospital for Diseases of the Chest. He continued his work in St. Leonards until last August, when a sudden cardiac attack compelled him to relinquish it. The chief interest of his life since 1912 was the radiology of the lungs, the importance of which he was one of the first to appreciate. His experience has been summarized in his published work *The Radiography of the Chest*, the first volume of which was published in 1920, and reviewed in our columns on June 12th, 1920 (p. 798); the second volume is now in the press. His other publications include many papers in the *British Medical Journal*, the *Lancet*, and the *Archives of Radiology and Electrotherapy*. He married in 1893 Robina Marion Orr, who survives him, together with one son, Dr. T. D. Overend, with whom he was in partnership.

JOHN ALEXANDER SUTHERLAND, M.B., C.M.,

Physician, North Bierley Joint Hospital.

Dr. JOHN ALEXANDER SUTHERLAND died on February 18th, in his 70th year, at his residence, Low House, Cleckheaton, after a few days' illness. A native of Dunbar, he was a distinguished pupil at the Edinburgh Institution. He graduated M.B., C.M. at the university in 1878, and during his student days was an energetic Volunteer and a good marksman in the university "Blacks." He served as one of the house-physicians in the Edinburgh Royal Infirmary in a group which included such well known names as those of Sir German Sims Woodhead, Sir James Mackenzie, and Sir George Berry, and he was also for a time house-surgeon to the Leith Hospital. With his lifelong friend Dr. John Stewart of Nova Scotia, he was instrumental in organizing ward entertainments for the patients. He commenced practice in Cleckheaton in 1880, and there the whole of his professional life was spent.

In addition to the work of a busy practice, Dr. Sutherland was a man of many activities and wide interests. He had been medical superintendent of the North Bierley Joint Hospital since its opening in 1890, and was formerly medical officer of health of the Cleckheaton
